Climate change is another potential risk factor to sustainable management of soil quality of cropland. The rate of increase of average temperature ranged from 0.4°C/decade at Nanyang to 0.61°C/decade at Zhengzhou and 0.71°C/decade at Luancheng, from south to north of HHH plains.^[14] Sunshine hours over the past 25 years (since 1985) decreased remarkably at both Zhengzhou and Luancheng but with a slightly declining trend at Nanyang. Annual mean precipitation in the HHH had a slightly increasing trend but with a slight decrease in Beijing. Climatic shifts in temperature and precipitation have a major influence on the decomposition and amount on SOC stored within a soil ecosystem.^[15] The SOC dynamics such as moisture, temperature, pH, and salt concentration in the topsoil will be affected by increase in temperature, precipitation, and groundwater depletion.

Groundwater depletion coupled with increase in temperature may lead to higher soil water transpiration, which will lead to pumping of more groundwater for irrigation. Furthermore, some soils of the cropland in the northern HHH region become rainfed cropland because of groundwater depletion. Consequently, salt in deep soil will move to surface layer by the higher transpiration if there is not enough groundwater for irrigation to leaching the salt into the subsoil. Therefore, the increase in salt concentration in topsoil will decrease SOC sink capacity and jeopardize soil quality.

The third challenge is from the agricultural intensification in HHH plain. SOC in the HHH has increased through agricultural intensification.^[5] Therefore, HHH has been treated as the leverage point to reduce the emission of GHG such as nitrous oxide and to reduce groundwater depletion.^[8] Thus, excessive intensification has to be shifted to sustainable or green intensification.^[16] As a result, managing soil quality of cropland in the HHH plain is becoming an arduous task for agronomist and soil scientists in China.

MANAGING SOIL QUALITY OF CROPLAND IN HHH PLAIN

Improve Soil Quality of Cropland by Reclamation

The improvement in soil quality in the HHH plain is affected by inherent soil characteristics and land use. Low-productivity soils (e.g., sandy and light soil and clayey soil) are distributed along the Huai, Huang He, and Hai rivers. These soil types are marginal croplands. Therefore, biocarbon practices may be used to alter soil texture, increase soil moisture reserves, reduce soil evaporation, and improve soil fertility.

Increase Soil Quality by Adopting Ecological Practices

A moderate level of cropland intensification can enhance SOC stock and reduce the depletion of groundwater. Thus, understanding principles and techniques to increase SOC stock and improve water use efficiency is a research priority. The adoption of best management practices for the HHH region [e.g., no-tillage (NT) farming, integrated nutrients management (INM) with the combined use of organic manure and balanced fertilizer, organic manure, improved grazing, and harvesting] is critical. The goal is to enhance the eco-efficiency of production systems and to improve the soil quality of cropland in the HHH region.

Measures to Improve SOC Stock

Adopting measures of increasing SOC stock and improving soil quality has numerous cobenefits (i.e., mitigating climate change and improving water quality). Therefore, incentivizing the farm household through carbon (C) trading and payments for ecosystem services is needed to improve soil quality. Well-planned measures may involve a series of steps as follows:

1. Cropland planning for increasing the SOC stock must be done on the basis of temperature, precipitation, soil subgroups, and the household factors and socioeconomic conditions. Detailed maps must be prepared for

the SOC stock at subregion and plot scales. Appropriate cropping systems must be outlined for subregional climate, water, and soil type. The rate of built-up of SOC stock must be evaluated, and the information was made available to policy-makers and the farm households.

2. Site-specific practices of improving SOC stock must be identified, such as the conversion of plow tillage to NT farming with mulching and use of cover crops, creation of positive C and nutrient budgets, reduction of nutrient losses by leaching and volatilization, minimization of soil disturbance, provision of a continuous ground cover by mulching and cover cropping, and use of INM strategies for applying manure and biofertilizers along with judicious use of chemical fertilizers.^[17]
3. Modus operandi must be developed for increasing SOC contents at the farm and community levels. The SOC stock is not only an indicator of soil quality but also a large C sink.^[18] Therefore, it is necessary to develop market-based mechanisms to trade soil C in the HHH region.

CONCLUSION

Soil quality of cropland in the HHH is critical to China's food security and environmental quality. Improvement in soil quality has built strong foundation for the increased yield of wheat and maize since the 1950s by a series of program funded by China central government. However, sustainable management of soil quality meets the major challenges from groundwater depletion, GHG emissions, excessive agricultural intensification, the potential adverse effects on salt, and moisture regimes affected by increase in temperature. Therefore, managing soil quality of cropland should take sustainable intensification, increase in SOC, and decrease in salt content as the researchable priority.

Fertilizers: Application Methods

John Ryan

Aleppo, Syria*

Abstract

As crop yields increase, even more fertilizer than used at present will be needed. The growth in demand will come particularly from developing countries where fertilizer usage is low and where populations are expanding rapidly. The twin concerns—efficient economic use and mitigating environmental damage, as well as maintaining nutritional quality of crops—underscore the continued importance of precise, accurate, and efficient application of chemical fertilizers.

INTRODUCTION

As the beginning of civilization, soil fertility has been a dominant factor influencing human destiny. It took millennia before humans could unravel the mysteries of soil nutrients in relation to crops. In the 19th century, the invention of superphosphate laid the basis for the chemical fertilizer industry, an essential component of modern agriculture. Developments in fertilizer technology have provided an array of commercial fertilizer types and formulations, including solids, liquids, gases, and suspensions; single elements to complex multinutrients; soluble to slow-release materials; pelleted and powder forms; and bagged and bulk materials.^[1] Soil chemistry–plant nutrition research has provided the technical basis for fertilizer application methods. Both research and legislation have evolved to address changing fertilizer technology and cropping systems. The chemical fertilizer industry, a complex global one, is the cornerstone of agricultural production and world food supplies through the provision of crop nutrients.^[2] The broad goals of nutrient management are in the following: 1) cost-effective production of quality crops; 2) efficient use of fertilizers; 3) maintenance of soil quality; and 4) protection of the environment. This brief review highlights fertilizer application methods within such a context.

FERTILIZER APPLICATION: BASIC CONSIDERATIONS

Decisions about sustainable and economical fertilizer use must consider many crop, soil, and environmental factors. Soil testing is a well-established practice for identifying the fertility status of the soil, nutrient constraints, and the need for fertilization, especially in the west,^[3] however, progress has also been made in developing countries in promoting soil testing, correlation, and calibration.^[4] It involves

representative field sampling; analyzing the sample in the laboratory using appropriate tests; interpreting the test data using established norms; and making fertilizer recommendations. Criteria vary with the nutrient in question, soil type, or management. Apart from nutrients, crop growth is indirectly influenced by soil factors such as acidity, salinity, sodicity, toxic levels of elements, e.g., boron, and by high nutrient “fixation” capacity. Soil physical constraints such as compaction and increased bulk density must also be considered.

Crop characteristics such as yield goal or predicted yield and specific nutrient uptake are considered in fertilizer recommendations. Thus, fertilizer nutrient needs vary widely between short- and long-season crops and within crops; the higher the uptake or demand at maximum yield, the more fertilizer is needed. The architecture and extent of the crop’s root system, including mycorrhizal colonization, dictate the relative use of soil and fertilizer nutrients and fertilizer application methods.

Environmental factors govern fertilizer-use efficiency. For example, frozen soil leads to poor nutrient penetration and runoff loss; rain after application promotes leaching losses; high ambient temperature promotes both crop growth and nutrient uptake; warm, windy conditions can increase ammonia (NH₃) volatilization; and increasing water use, from rainfall or irrigation, enhances the uptake of fertilizer nutrients. Strategies to adapt to such conditions include splitting the fertilizer rates to coincide with crop growth demand, with due consideration of rainfall, and soil incorporation of nitrogen (N) fertilizers to minimize loss.

FERTILIZER APPLICATION METHODS

Given the variability of chemical fertilizers (physical state, type of nutrient, solubility, release rates) and range of crops (field, greenhouse, annual, perennial), fertilizer management conditions (rainfed, irrigated), and economic

considerations, fertilizer application methods have correspondingly changed.^[1] The application methods used should be accurate, efficient in terms of nutrient use, and economic in terms of comparative investment. Fertilizers can be applied during soil preparation and before planting the crop, i.e., the more traditional approach, and/or after crop emergence (Table 1). With increased fertilizer use and greater emphasis on efficiency, fertilizers can be applied by broadcasting, banding, or with water, i.e., foliar sprays and in irrigation water.

Table 1 Fertilizer application methods.

Application time/method	Attribute (+/-)	Remarks
1. Preplant		
Broadcast	+	Traditional, suitable for solids/liquids
	-	Less efficient for P, could cause NH ₃ loss
Injection	+	Reduces NH ₃ loss, suitable for immobile nutrients
	-	More expensive, elaborate equipment needed
2. Planting time		
With seed	+	Efficient, economic
	-	Needs machines, possible damage to germination, especially with N
Band placement	+	More efficient for P in high-fixing soils
	+	Can use liquids and solids
3. Postemergence		
Side dressing	+	Suitable for P and K
	-	Needs care with N
Topdressing	+	Suitable for cereals, perennial crops
	+	Solids and liquids can be used
4. Fertigation		
	+	High water and N-use efficiency
	-	High initial costs and maintenance
	-	Need soluble nutrient sources
	-	Inline precipitation, poor soil mobility with P
5. Foliar sprays		
	+	Suitable, effective where soil application is not possible
	+	Good for micronutrients, especially in perennial crops
	-	May not supply full N, P, K requirement
	-	Several sprayings needed
	-	Limited N concentration (1–2%), also biuret

Broadcasting

The essence of broadcasting fertilizer involves spreading the material evenly on the bare or cropped soil. Prior to the age of mechanization, solid-form fertilizer was spread by hand and is done so in many developing countries. Mechanized application represented a major improvement in speed, accuracy, and uniformity of spreading. The range of such equipment varies from small to large, and from pull-type drop-spreaders to self-propelled machines with power-driven, disc spreaders. Generally, the application rate of fertilizer in such machines is determined by their ground speed. Large, bulk fertilizer spreaders have flotation types to mitigate soil compaction.

Topdressing is essentially broadcasting over the established crop; it is the only feasible means for pasture and perennial forage crops and flooded rice. Fertilizer-use efficiency and reduced adverse environmental effects are promoted with splitting the fertilizer application between planting and a later crop growth stage. Thus, depending on the standing crop, its nutrient needs, and growing conditions, application of fertilizer to the crop stand is a common practice. Topdressing may be done several times with long-season crops. Plant analysis can help in determining the need for such applications.

The use of liquid fertilizers is a new development, mainly in the United States for N fertilizers; liquids can be sprayed or dribbled on the soil surface in bands between rows with gravity feed. Where spraying is involved, there is need for a tank, pump, pressure gauge, nozzles, fittings, and a spreading boom; it can have variable traction mechanisms, many tractor mounted. In the age of precision agriculture, sophisticated and expensive machinery is used to variably apply the fertilizer, liquid or solid, across a given field having different fertility levels, as determined by soil analyses, whose spatial variability is determined by global positioning systems.

Placement/Banding

The main approach to fertilizer application at planting time is with the seed or by banding. When applied with the seed, application rates must be limited for avoiding seedling damage and poor emergence, especially with N fertilizers and those with a high “salt index.” Banding implies application of fertilizer a few centimeters to the side and below the seed row. Fertilizer and seed are usually in the same drilling machine, but in parallel hoppers; both are delivered by metered gravity feed through tubes behind the shoe or disc. Banding reduces P fixation, and hence increases fertilizer-use efficiency. The efficiency of N fertilizer, alone or with P, is also increased.

The placing of the fertilizer, usually liquids, at some depth in the soil, via tool bar-mounted knives in shank openers, is referred to as injection or “knifing in.” It helps

reduce or eliminate volatile loss of N fertilizers such as urea and ammonium compounds, and, to a lesser extent, it places immobile nutrients like phosphorus (P) closer to the root zone and also reduces nutrient losses due to erosion and runoff. This can be done before planting or after crop emergence.

As with preplant application, liquids such as anhydrous NH_3 can be injected under pressure into the soil between or close to the seed rows; use of solid materials is less common by this method. Placement can be combined with row cultivation. The type of fertilizer must be considered; both P and potassium (K) should be close to the roots as they are immobile. Plant damage due to high localized NH_3 concentrations, as well as disruption of plant roots, must be avoided.

Fertigation

The practice of applying water and fertilizers together, fertigation, involves technical and economic advantages, e.g., savings in labor, time, and equipment and fuel costs.^[5] Open fertigation systems involve the metering of soluble solid or liquid fertilizer, mainly N, into irrigation ditches. However, volatile NH_3 gas loss can occur when the N source is urea or anhydrous NH_3 . Simultaneous application of sulfuric acid (H_2SO_4) can counteract the alkalinity and rise in pH following NH_3 application;^[6] it also prevents calcite precipitation,^[7] thus reducing the water's sodium absorption ratio and increasing infiltration. P is less suitable for open-channel application because it can be readily precipitated and thus be unevenly spread within the field. Where soils are sodic and have poor hydraulic characteristics, amendments such as polysulfides, gypsum, and H_2SO_4 can be readily metered into the irrigation system.

Closed fertigation systems involve fertilizer applied to irrigation water in pipes under pressure with pumping, e.g., sprinklers and trickle or drip irrigation, with many variations of the latter system; fertilizer solubility and subsequent nutrient movement in the soil are considered. As most N fertilizers are water soluble, N is easily used in both systems; K sources are soluble but relatively immobile and remain in the top few centimeters of soil or at the point of dripper. The primary concern with P fertilizers is poor solubility, precipitation, and limited mobility at the dripper site. With calcium (Ca)-rich water, soluble P forms precipitates in the tubing that can block the tiny orifices, thus rendering the system ineffective. Flushing with acids such as urea phosphate and phosphoric acid can dissolve such precipitates. Acidic solutions promote greater P mobility in the wetted soil volume and by dissolving insoluble soil P sources, namely $\text{Ca}_3(\text{PO}_4)_2$.^[8] Acidic P solutions may also enhance micronutrient availability in calcareous soils.

While close-system irrigation is a sophisticated technology, there are many obstacles to using fertilizers in such

systems. However, these obstacles are well understood by commercial farmers and irrigation company personnel, and workable solutions are readily available. As a consequence, fertigation is part of high-intensity production systems in field and under greenhouse conditions.

Foliar Feeding

The concept of applying nutrients as foliar sprays is relatively new and is a practice adapted in situations where soil application of fertilizers is ineffective and where a quick growth response is required.^[9] Aerial application of nutrients in sprays is used for broadacre crops where the equipment has problems entering or crossing the field and where large areas need to be sprayed or where nutrient uptake is limited by cold. Such nutrients can be normally combined with pesticides using ordinary pesticide sprayers; however, compatibility and stability of the ingredients must be considered.

However, as with any technology, there are pitfalls and obstacles. Fertilizer solution is a salt solution and as such can injure growing plants. Thus, nutrient concentration in the sprayed solution should be no greater than 1–2%. While urea is suitable for foliar sprays, the concentration of biuret, a toxic component, should be limited. Other practical considerations associated with foliar application involve varying the nutrient application relative to the irrigation spray and applying nutrient sprays frequently where the permissible concentrations of nutrients are low with respect to the growing crop needs, especially for major nutrients. However, one or two sprayings with micronutrients are usually sufficient to alleviate the deficiency.

CONCLUSION

As crop yields increase, even more fertilizer than used at present will be needed. The growth in demand will come particularly from developing countries where fertilizer usage is low and where populations are expanding rapidly. The twin concerns—efficient economic use and mitigating environmental damage, as well as maintaining nutritional quality of crops—underscore the continued importance of precise, accurate, and efficient application of chemical fertilizers. A major part of world food production is attributable to chemical fertilizers. This will continue—there is no alternative. But the industry must be sensitive to societal concerns. While the emphasis will continue to be on the environment in the developed world and on production in the developing countries, efficient fertilizer application technology can accommodate both concerns. Fertilizer application will, in future, be part of strategies of “positive soil fertility management,” where the broader perspective will apply, i.e., consideration of the whole cropping system—not just 1 year's

crop—and the residual or carryover value of the added fertilizer. Indeed, its implications for the entire food chain cannot be ignored. While research will continue to achieve even greater efficiencies of application, the greatest challenge will be to transfer what is known to those who need it most, especially in the developing world.

Fertilizers: Leaching Losses

Paul G. Saffigna

Tropical Forestry, University of Queensland, Gatton, Queensland, Australia

Ian R. Phillips

School of Environmental Engineering, Griffith University, Nathan, Queensland, Australia

Abstract

Leaching is the downward movement of fertilizer or waste in soil with the drainage water and is a critical process in global nutrient cycling. To be available for plant uptake, fertilizer/waste (solute) must dissolve in the soil water. The combination of soil water and dissolved solute is the soil solution. The soil solution and soil air are present in the pores between soil particles. If water fills all the pores and no air is present, the soil is saturated and leaching is rapid. If both water and air are present, the soil is unsaturated and leaching is slower.

INTRODUCTION

Efficient nutrient use occurs when the plant demand coincides with the presence of solute in the root zone. When solute leaches below the root zone, it is unavailable for plant uptake and is lost from the soil–plant system. Depending on the amount of water draining below the root zone, the leached solute may simply accumulate at depth in the soil or it may pollute the underlying groundwater.^[1,2] Pollution of groundwater by fertilizers and waste is a major environmental problem worldwide.^[1] Although substantial progress has been made in understanding the movement of fertilizers and wastes in soil, the words of Leonardo da Vinci are equally applicable today as they were 500 years ago: “We know more about the movement of celestial bodies than about the soil underfoot.”

THE MECHANISMS AND PATTERN OF LEACHING

Water movement due to gravity causes leaching.^[3] When there is no mixing between the solute and the draining water, the solute is pushed ahead of the advancing water like a piston and remains in a narrow zone or band. This somewhat idealized leaching pattern is referred to as *piston flow* (Fig. 1B). Commonly, mechanisms such as dispersion, ion exchange, and ion exclusion modify this leaching pattern. *Dispersion* is a result of solute mixing with the drainage water by molecular diffusion^[3] and/or hydrodynamic dispersion^[3,4] and causes solute to be more “spread out” in the soil than if only piston flow occurred (Fig. 1C). The process of *cation exchange* with negatively charged soil colloids^[5] slows the rate of cation leaching in soil, reduces the number of cations in the soil solution, and skews the fertilizer leaching pattern (Fig. 1D). *Exclusion* of negatively

charged solute ions such as nitrate and chloride (Cl) by the negatively charged soil colloids^[3] confines them to the middle of the soil pores. Here water drains faster due to reduced friction, causing solute to leach more quickly than if piston flow alone was occurring (compare Fig. 1E with Fig. 1B).

MEASUREMENT AND MODELING OF LEACHING

Although the pattern of leaching is well represented by the examples shown in Fig. 1, this does not provide sufficient information to measure leaching losses. By multiplying the concentration of solute by the volume of drainage water, the amount of solute leached from the soil can be quantified. Representative samples of soil solution are critical for quantifying solute leaching.^[6] Column displacement and centrifugation are commonly employed to extract soil solution in the laboratory, while tension lysimeters are commonly used in the field. The volume of water draining through soil can be measured using repacked soil cores, intact (undisturbed) soil cores, and field lysimeters (undisturbed or refilled). These methods can be used to quantify the key mechanisms controlling the rate and magnitude of solute leaching in the laboratory and field.^[7]

Modeling solute leaching in and below the plant root zone is important for predicting soil water quality and for developing fertilizer and waste management practices which minimize adverse environmental impacts. Numerous analytical and numerical models have been developed which include key physical and chemical processes that affect solute leaching.^[8] Water flow models, solute transport models, and aqueous chemical equilibrium models were often developed independently, and solute leaching models mostly considered only a

Fig. 1 Schematic representation of solute leaching in soil. (A) Solute distribution pattern prior to leaching—note that the solute band contains 12 cations (•) and 12 anions (○) (24 ions); (B) Solute distribution pattern after leaching involving piston flow only—note that the solute band still contains 24 ions and has only been moved deeper in the soil; (C) Solute distribution pattern after leaching involving piston flow and dispersion—note that the solute band has become more spread out but still contains 24 ions; (D) Solute distribution pattern after leaching involving piston flow, dispersion, and exchange—note that the solute band only contains seven cations, is skewed in shape, and is at a shallower depth than (B); (E) Solute distribution pattern after leaching involving piston flow, dispersion, and exclusion—note that the solute band still contains 24 ions but has moved deeper in the soil than (B).

single ion and simplified chemical processes. There has been a conscious effort to couple leaching models for water flow and solute transport with chemical equilibrium models.^[9]

MAGNITUDE OF LEACHING

Not all nutrient elements are susceptible to leaching, and the amount of a nutrient lost by leaching varies widely between climates, land use, soils, and nutrients (Table 1).^[10]

Generally, fertilizer-leaching losses are greatest in sandy soils, moderate in loamy soils, and least in clay soils for two

reasons. Firstly, water drains faster in sandy soils, which have a low capacity to retain cations. Secondly, anions tend to leach faster than cations because soils carry mainly negative electrical surface charge. For example, after adding 50, 200, or 1000 kg/ha of potassium chloride to a clay soil, about 7, 8, and 6 kg/ha of potassium (K) was leached below the root zone, whereas in a sandy soil receiving the same fertilizer rates, 7, 20, and 240 kg/ha of K was leached.^[14] In both of these soils, nearly all of the added Cl leached below the root zone. Nitrate (200 kg/ha of nitrate–nitrogen) and Cl leaching to depths >5 m and into the underlying groundwater have been found in sandy soils within 1 year of fertilizer application.^[1,11]

Table 1 Leaching losses from agriculture under different climates and land uses.

Country	Land use	Nutrient	Form	Rate applied (kg/ha/yr)	Amount leached (kg/ha/yr)	Reference
United Kingdom	Grazing	N	Fertilizer	250	4–184	[10]
United Kingdom	Grazing	N	Fertilizer	500	88–590	[10]
Europe	Cropped	N	Fertilizer	80	47–74	[10]
United States	Potatoes	N	Fertilizer	265	200	[11]
United States	Potatoes	Cl	Fertilizer	360	300	[11]
Australia	Bare	P	Wastewater	50	2–6	[12]
Australia	Bare	N	Wastewater	180–1500	113–315	[12]
Australia	Bare	K	Wastewater	300–2040	1–280	[12]
Australia	Cropped	Ca	Wastewater	185–530	127–330	[12]
New Zealand	Grazing	N	Wastewater	200–400	6–10	[13]
New Zealand	Grazing	N	Fertilizer	200–400	8–17	[13]
New Zealand	Bare	K	Fertilizer	50	1–8	[14]
New Zealand	Bare	K	Fertilizer	200	6–22	[14]
New Zealand	Bare	K	Wastewater	1000	20–240	[14]
New Zealand	Bare	Mg	Fertilizer	62	0.6–17	[14]

Although there are many benefits from using organic wastes as nutrient sources, their long-term environmental impact is a major concern. Sewage sludge can contain heavy metals (copper, lead, cadmium, and zinc) which can contaminate soils, while the use of wastewater can introduce very high concentrations of unwanted nutrients (nitrogen, Cl, and K), which can increase the likelihood of groundwater pollution. Generally, leaching of inorganic (fertilizer) phosphorus (P) is negligible; however, P leaching (ca. 10% of applied) has been observed in a wide range of soils treated with wastewater. The major source of wastewater P is dissolved organic P, and organic P compounds are relatively stable and mobile in soils. Consequently, the sustainability of long-term wastewater application to soil is a major environmental concern for many countries.

MITIGATION AND MANAGEMENT OF FERTILIZER NUTRIENT LOSSES

The amount of solute leached from soil is highly dependent on dissolved nutrient type (cation or anion), concentration and form (ionic or complexed), chemical, physical, and biological properties of the soil, timing and placement of fertilizer application, rainfall, and irrigation practice. For example, large leaching losses of fertilizer nitrogen occur if: it is present as nitrate; there is limited plant uptake; and the soil is permeable (well drained) and located in a high rainfall environment. Mitigation of fertilizer leaching is site specific and highly dependent on site management practices. Recommended management strategies include: 1) synchronization of fertilizer supply with crop demand and 2) employing irrigation strategies to minimize the drainage of soil water and loss of nutrients from the plant root zone. Other strategies include the use of nutrient release inhibitors, slow release fertilizers (maintains low-nutrient concentrations in the soil solution), and incorporation of amendments (zeolite, iron oxides, gypsum, and fly ash) into soil that remove fertilizer nutrients from the soil solution. There is an urgent need to develop best management practices for land disposal of organic wastes as these nutrient sources are likely to have a greater effect on soil and water pollution than fertilizers.

Abstract

Mineral fertilizers, also known as chemical fertilizers (hereinafter mineral fertilizers are also referred to as fertilizers), refer to the products manufactured by the chemical fertilizer industry through chemical reactions of different elements or products. Nitrogen (N), phosphate, and potash fertilizers are primary mineral fertilizers produced by the fertilizer industry. N fertilizer products are mostly manufactured from ammonia (which is derived from chemical reaction of N and hydrogen). Phosphate fertilizers are derived by reacting phosphate rock with sulfuric or phosphoric acid, and potash fertilizers are refined from mined potash ores or sea brines.

INTRODUCTION

Harvested crops remove nutrients. Unless the removed nutrients are replenished, soil fertility declines and the capacity of the soils to produce additional crops degrades. To maintain soil health and productivity, nutrients must be continuously replaced. Because natural processes can replenish only limited quantities of the nutrients removed, these nutrients must be supplied from external sources including organic materials, biological fixation, and mineral fertilizers. Although organic and biological sources are important in supplying nutrients, these are not sufficient to meet the nutrient requirements of the food and fiber production needed for an ever-growing world population. World population increased from less than two billion at the turn of the 20th century to over six billion at the beginning of the 21st century and may reach over nine billion by 2050.^[1–3] Since the mid-1960s, mineral fertilizers have played an important role in promoting cereal production, especially in developing countries (Fig. 1).

MAIN FERTILIZERS—NUTRIENTS AND PRODUCTS

There are more than 100 chemical elements in nature but only 16 are considered essential for plant growth. If any of these 16 elements are lacking, plants cannot complete their vegetative or reproductive cycles. Thirteen of these are “mineral” nutrients (Table 1). Some of these nutrients combine to form compounds that compose cells, enzymes, etc. Others must be present in order for certain chemical and physiological processes of the plant to occur. A productive

soil should contain all the essential plant nutrients in sufficient quantity and in balanced proportions. Soils differ widely in their ability to provide the essential nutrients for plant growth, depending on the total amount of nutrient native to the soil and the mobilization or fixation reactions in the soil that affect the chemical form and resulting availability of the nutrients. When the nutrient supply from the soil is insufficient for crop needs, additional nutrient can be supplied by fertilizer to compensate for the difference. The type and the amount of fertilizer required depend on the crop to be grown and the soil characteristics.

The nutrients taken up by plants from mineral fertilizer products are in the same form as the nutrients taken up from organic sources, but many different products have been developed to meet specific needs for crop production.

Simple Fertilizers vs. Complex Fertilizers

Simple fertilizers contain only one primary plant nutrient. In contrast, complex fertilizers contain two or more plant nutrients. Complex fertilizers are produced by the processes involving chemical reaction between the constituents containing the primary plant nutrients (ammonium phosphates, nitrophosphate, NPK fertilizer, etc.). Fertilizers produced by granulating together single-nutrient materials or mixing granules of single-nutrient fertilizers are referred to as compound or mixed fertilizers. The nutrient content of fertilizer products, or “grade” expressed as a percentage, may refer to either the total or available nutrient content, and may be expressed traditionally for some nutrients in the oxide form [phosphorus pentoxide (P₂O₅) and potassium oxide (K₂O)].

Fig. 1 Fertilizer use and cereal production in developing countries 1961/62–2002/03.

Source: Data from Food and Agriculture Organization of the United Nations (FAO).^[4]

Conversion factors from oxides to elements are as follows: $P = 0.436 P_2O_5$, $K = 0.830 K_2O$. Thus, 100 kg of 12:6:6 fertilizer contains 12 kg of N, 6 kg of P_2O_5 , and 6 kg of K_2O , respectively.

Table 1 Essential mineral nutrients and their chemical symbols.

	Principal chemical form taken up by plants	Nutrient uptake by wheat (5 mt/ha) (kg nutrient/ha)
Primary nutrients		
Nitrogen (N)	NH_4^+ , NO_3^-	105
Phosphorus (P)	$H_2PO_4^-$	18
Potassium (K)	K^+	15
Secondary nutrients		
Sulfur (S)	SO_4^{2-}	8
Magnesium (Mg)	Mg^{2+}	6
Calcium (Ca)	Ca^{2+}	2
Micronutrients		
Chlorine (Cl)	Cl^-	3
Iron (Fe)	Fe^{2+}	0.2
Manganese (Mn)	Mn^{2+}	0.2
Zinc (Zn)	Zn^{2+}	0.2
Copper (Cu)	Cu^{2+}	0.03
Boron (B)	H_3BO_3	0.02
Molybdenum (Mo)	MoO_4^{2-}	
Essential non-mineral nutrients		
Carbon (C)		
Hydrogen (H)		
Oxygen (O)		

N Fertilizers

N fertilizers can broadly be classified into four groups depending on the chemical form in which the N is present in them: ammonium fertilizers, nitrate fertilizers, combined ammonium and nitrate fertilizers, and amide fertilizers (Table 2). Also, there are NPK complex fertilizers, mixed compounds such as granular compound fertilizers, and bulk blends.

N fertilizers are completely water-soluble, and most sources are essentially equal in effectiveness for crops if incorporated into well-drained soils. If the N source applied is in the nitrate (NO_3^-) form, it is immediately available for plant uptake. If it is applied in the ammonium form, NH_4^+ is initially absorbed by the soil organic matter and clay particles. Under soil conditions suitable for good plant growth, however, the ammonium form is rapidly converted by nitrifying bacteria to the nitrate form (nitrification). Because the nitrate is not absorbed strongly by soil particles, it moves freely in soil water. For maximum uptake of N fertilizer, plants must be in a vigorous growth stage soon after the N is applied. Otherwise, the nitrate may move below the root zone.

Phosphate Fertilizers

Phosphate fertilizers vary widely in solubility. Phosphate rock is essentially insoluble in water and is only slowly available to plants if applied directly to the soil. Phosphate rock, however, is the basic raw material from which the most typically used phosphate fertilizers are produced. The main deposits and production units of phosphate rock are located in United States, Morocco, Togo, Senegal, Tunisia, Russia, Jordan, China, and Oceania.

Table 2 Fertilizer materials.

Fertilizer products	Grade (%)		
	N	P ₂ O ₅	K ₂ O
N fertilizers			
Ammonium fertilizers			
Anhydrous ammonia	82		
Ammonium sulfate (AS)	21		
Ammonium chloride	26		
Nitrate fertilizers			
Calcium nitrate	16		
Sodium nitrate	16		
Ammonium nitrate fertilizers			
Ammonium nitrate (AN)	34		
Calcium ammonium nitrate (CAN)	21		
Ammonium nitrate-sulfate	26		
Amide fertilizers			
Urea	46		
S-coated urea	35		
Calcium cyanamide	22		
Multinutrient fertilizers			
Nitrophosphate (NP)	21	21	
Mono-ammonium phosphate (MAP)	11	52	
Diammonium phosphate (DAP)	18	46	
Liquid ammonium polyphosphate	12	40	
Urea ammonium phosphate	28–32	30	
Phosphate fertilizers			
Water-soluble types			
Single superphosphate (SSP)		18	
Triple superphosphate (TSP)		46	
Partly water-soluble types			
Partially acidulated phosphate rock		(23–26)	
Slow-acting types			
Dicalcium phosphate (citrate soluble)		40	
Basic slag		9	
Calcium metaphosphate		62	
Very slow-acting types			
Rock phosphates		<32	
K fertilizers			
Muriate of potash (potassium chloride) (MOP)			60
Sulfate of potash (potassium sulfate) (SOP)			48
K-Mag/sulpomag (K, Mg sulfate)			23
Nitrate of potash (potassium nitrate)	13		44
Potassium polyphosphate		59	39

The rock can be solubilized by direct acidulation with sulfuric acid to form SSP or to produce phosphoric acid. The phosphoric acid can then be used to directly acidulate more phosphate rock to form TSP or the acid can be reacted with ammonia to form ammonium phosphates. The availability of the phosphorus to the plant is typically expressed as the sum of the water- and citrate-soluble P in the fertilizer source. Water-soluble P is easily available to plants, while citrate-soluble P is more slowly available to plants. The soluble P, however, can react with other minerals in the soil, thus reducing the immediate availability to plants. This transformation can be retarded somewhat through granulation and placement of the fertilizer. The P products formed in the soil, however, limit the movement of P in the soil and result in a longer term “residual value” not observed with N. Generally, the agronomic performance of phosphate fertilizers containing 60% or more water-soluble P is essentially equal to that of fertilizers containing 100% water-soluble P.^[5]

Potash Fertilizers

Canada has the world's largest known deposit of K. Potash is also mined in France, Germany, Italy, Spain, England, Israel, Jordan, Russia, Belarus, Ukraine, Brazil, and China. Potassium chloride (KCl) accounts for more than 90% of the K sold in North America. As with most of the common potash fertilizers, KCl is water soluble, whereas the concentration of K in KCl is high 60% and the concentration of chloride in KCl is about 45% and, therefore, potassium sulfate is often used for chloride-sensitive crops such as tobacco and to supply S. Sulfate of potash-magnesia contains not only potash but also about 11% Mg and 22% S. It is a good source of water-soluble K and Mg, and is important where Mg and/or S is deficient, or with Cl-sensitive crops. Potassium nitrate contains little or no Cl or S and is completely water soluble. It is widely used in foliar spray applications for fruit, vegetables, and cotton.

After application, most of the K from mineral fertilizer is absorbed near the application point in the soil by clay minerals and organic matter like ammonium N. It thus becomes “exchangeable” K. However, unlike ammonium N, which converts to a mobile form, K continues to be held in the soil and is relatively immobile.

Secondary and Micronutrients

While the nomenclature of secondary nutrients (Ca, Mg, and S) and micronutrients (Cl, Fe, Mn, Zn, Cu, B, and Mo) may indicate a lower degree of importance relative to N, P, and K, these nutrients are just as important to plant nutrition as the primary nutrients. They are referred to in this manner

Fig. 2 World: N, phosphate, potash, and total NPK consumption, 1961/1962–2002/2003.

Source: Data from Food and Agriculture Organization of the United Nations (FAO).^[4]

because plants do not usually require as great a quantity of them. Calcium is generally supplied in the limestone (calcitic or dolomitic) used to reduce soil acidity or in basic slag from the steel industry or gypsum. The most common source of magnesium is dolomitic limestone. Other sources include potassium–magnesium sulfate, magnesium sulfate, magnesium oxide, and basic slag. Most fertilizer S sources are sulfates (ammonium, K, or magnesium) that are moderately to highly water soluble and are quickly available to plants. Elemental S (>85% S) can also be used as a fertilizer, but it results in a slower crop response because it is water insoluble. If well incorporated into the soil in advance of planting, however, elemental S is an agronomically effective and economically efficient S source.

While there are many fertilizer sources available to correct micronutrient deficiencies, some of the more common are borax (11% B), copper sulfate (23% Cu), iron sulfate (19–23% Fe), iron oxide (69–73% Fe), manganese sulfate (26–30% Mn), manganese oxide (41–68% Mn), ammonium molybdate (54% Mo), sodium molybdate (40% Mo), zinc sulfate (23–36% Zn), and zinc oxide (78% Zn). Cu-, Fe-, Mn-, and Zn-chelates are also common fertilizer sources.

FERTILIZER USE: HISTORY AND TRENDS

Although the first use of mineral fertilizers was introduced during the early 20th century, large-scale use of mineral fertilizers started only after World War II—initially as a result of the use of surplus ammonia capacity remaining from the production of explosives during the war and then as a result of the introduction of fertilizer-responsive improved crop varieties during the Green Revolution era.

At the turn of the 20th century, fertilizer use was insignificant. By 1950, it increased to 14 million nutrient tons, and by 1960, total nutrient use was about 28 million tons.^[6,7]

After the mid-1960s, because of the adoption of the Green Revolution technologies, fertilizer use increased rapidly—reaching 85 million tons in 1973/1974 and 146 million nutrient tons in 1988/1989 (Fig. 2). Thereafter, global fertilizer use decreased because of a steep decline in fertilizer use in the transitional markets (Eastern Europe and Eurasia). These markets are in-transition from centrally planned economies to free market economies. Policy reforms in Africa and Latin America and agricultural policy changes in the developed markets also contributed to this process (Fig. 3). After declining to a low of 120 million tons in 1993/1994, global fertilizer use recovered slowly to reach 142 million tons in 2002/2003. Yet, it was lower than the peak of 146 million nutrient tons that was reached in 1988/1989.

During the 1990s, while fertilizer use was declining in the transitional markets and was nearly stagnant in the developed markets, it continued to grow in the developing markets—mostly in Asian economies. Consequently, the developing markets' share of global fertilizer use increased from 34% in 1980/1981 to 66% in 2002/2003. China, United States, India, Brazil, and France are five main users of mineral fertilizers in the world. These countries account for 60% of the global fertilizer use.

Fertilizer Use by Nutrients and Products

In 2002/2003, global use of N, P₂O₅, and K₂O was estimated to be 84.7, 33.6, and 23.3 million nutrient tons, respectively. Nutrient use by different regions is shown in Table 3. East Asia, South-West Asia, and North America are dominant users of N and P₂O₅. In K₂O use, Latin America dominates South-West Asia. Transitional markets account for less than 5% of global fertilizer use.

Urea, DAP/MAP, and MOP are the main fertilizer products manufactured by the fertilizer industry. These products accounted for over 50% of global fertilizer use

Fig. 3 Total fertilizer use by markets, 1980/1981–2002/2003.

Source: Data from Food and Agriculture Organization of the United Nations (FAO).^[4]

in 2002/2003 (Table 4). Other commonly used products are AS, AN/CAN, SSP, TSP, and NPKs.

Rapid growth in fertilizer use during the 1970s and 1980s also induced growth in fertilizer production and trade.

Table 3 Fertilizer use by regions and markets, 2002/2003.

Market/region	N (million nutrient tons)	P ₂ O ₅ (million nutrient tons)	K ₂ O (million nutrient tons)	Total (million nutrient tons)
Developed markets	22.9	8.9	8.5	40.2
North America	12.5	4.5	4.9	21.9
Western Europe	9.1	2.9	3.2	15.1

South/West Asia are dominant producers of N and P₂O₅, whereas K₂O production is mostly concentrated in Eurasia and North America.

Fertilizer Use Efficiency

Because of rapid growth in fertilizer use in the past, little attention was paid to the efficiency of fertilizer use. Overall, fertilizer efficiency may not exceed 40%. N use efficiency may vary from 30% to 50% for rice, maize, and sorghum in developing countries.^[12] Phosphorus and K use efficiencies are also low. Improving fertilizer use efficiency by proper placement and timing of fertilizer products and soil- and crop-specific recommendations could lead to a win-win situation by increasing crop productivity and reducing nutrient losses to the atmosphere thereby protecting the environment. New technologies of precision agriculture may prove useful in improving nutrient use efficiency by targeting fertilizer applications more accurately.

CONCLUSION

At the turn of the 21st century, the world faces many challenges. First, food production must be increased to eliminate hunger and malnutrition and ensure food security for all. Second, natural resources, such as rain forests, wildlife habitats, and biodiversity, must be protected. Third, soil degradation and nutrient depletion must be halted. Fourth, global warming and pollution must be reduced.

In confronting all these challenges, increased and environmentally sound use of mineral fertilizers will be essential for enhancing the productivity of cultivable lands, so that more food could be produced while protecting the environment by sparing forests and marginal lands, replenishing the removed nutrients, and sequestering carbon in the biomass production and the soils.

Because of uncertainties associated with events, it is difficult to make precise projections. However, one study estimated that annual fertilizer use should increase to 263 million tons to satisfy the food production requirements in 2020.^[13] This means that fertilizer use should be nearly doubled. Given the successes of the past (over five-fold increase in fertilizer use during the 1960–1990 period), this may not be a difficult target to achieve but would require a strong commitment from all stakeholders including donors and policymakers.

Fertilizers: Organic

Gary J. Gascho

Crop and Soil Sciences Department, University of Georgia, Tifton, Georgia, U.S.A.

Abstract

By one definition, organic fertilizers may be nutrient sources that can be used in organic farming. Organic fertilizers have been used for thousands of years. Ancient people principally used animal wastes to enhance the growth of plants, usually with great success. Guano, a commercial organic material from the excreta of seabirds and bats, was an important fertilizer in the Southern United States in the early 1900s. The application of organic fertilizers has become much more complicated, as modern municipal and industrial products, by-products, and wastes must be considered.

INTRODUCTION

By one definition, organic fertilizers may be nutrient sources that can be used in organic farming. With such a definition, inorganic materials that are deemed to be “natural,” such as mined gypsum, untreated salts, unprocessed lime, etc. can be included.^[1] For this entry, we define organic fertilizers as those that are organic, from a chemical standpoint. Only an overview of the subject can be provided in this brief contribution. More comprehensive publications are available.^[1,2]

ANCIENT APPLICATIONS OF ORGANIC FERTILIZER MATERIALS

The first fertilizers were organic. They have been used for thousands of years, and the literature is voluminous. Ancient people principally used animal wastes to enhance the growth of plants, usually with great success. Guano, a commercial organic material from the excreta of seabirds and bats, was an important fertilizer in the Southern United States in the early 1900s. The application of organic fertilizers has become much more complicated, as modern municipal and industrial products, by-products, and wastes must be considered.

GENERAL ADVANTAGES AND DISADVANTAGES OF ORGANIC FERTILIZERS

Agriculture occupies a great proportion of the land mass in comparison to industrial operations. It is quite natural that a disposal philosophy exists. Unwanted wastes are often promoted as beneficial for farm crops, sometimes only to remove the wastes from manufacturing sites or to save costly landfilling. Agriculture should make careful assessments of all fertilizer materials applied but especially of industrial and municipal wastes. That assessment should

include not only the nutrient value in relation to need but also the concentration of elements and compounds that could lead to crop and/or soil toxicity. The concentrations of heavy metals are a primary concern in many cases. When applying wastes containing the acceptable concentrations of heavy metals, careful maintenance of soil pH at >6.0 can help limit their release in the soil and availability to plants.

A general advantage of organic fertilizers can be the cost of nutrient, but that is not always the case. It largely depends on the proximity of the organic fertilizer to the site of application and the value of the organic. In cases where a material must be placed in a landfill, the material may have a negative value due to the cost and maintenance of that landfill. If so, a material may be obtained at little or no cost, or even at a negative cost. As organic fertilizers generally have lesser nutrient values than modern manufactured inorganic fertilizers, the cost of transportation per unit of nutrient is often the controlling factor in value of the fertilizer. A second potential advantage of organic fertilizers is that they may provide nutrient release over an extended period of time; in particular, nitrogen (N) can be mineralized over a season to eliminate the need for repeated applications. Soil organic matter can be increased when organic fertilizers are applied at sufficient rates. The value of soil organic matter is well recognized, but the ability of added organic matter to substantially add to the pool of soil organic matter is debatable. It greatly depends on many factors, especially climatic conditions.

General disadvantages of organics are their fertilizer ratios that are not likely to be matched to plant needs, their non-uniform composition that can prohibit precise uniform applications, and their unpredictable release of nutrients that may not coincide with the time a particular nutrient is most required by a particular plant. Some organic fertilizers may also contain unwanted, harmful, and/or toxic elements or compounds making them unsatisfactory for utilization. Some may be objectionable due to strong smells or irritants to humans. This latter disadvantage is important

to the quality of life in residential developments near the sites of application.

ANIMAL RESIDUES

Manures

Animal manures were the first fertilizers used in agriculture. Feces and urine from large animals and feces from poultry are the main sources. Most are applied, together with the bedding material, directly to the soil and usually in near proximity to the confined animals. Some are composted and/or pelleted to provide a material that is more agreeable for handling and transport. Nutrient composition can vary widely depending on the animal, its feed, the bedding, and the proportion of manure to bedding, and handling or storage prior to the application (Table 1).

Because of the importance of animal agriculture, manures will continue to be important sources of fertilizers and pose problems for agriculture and society. As farmers move toward precision applications (that provide improved nutrition without overapplication that can result in pollution of soil or water), it becomes increasingly important to analyze manures and apply them in accordance with plant needs. Analyses provided indicate that phosphorus (P) composition is highly relative to N for most plant needs. Therefore, application according to N needs provides too much P that may be bioavailable and add to the *eutrophication* of water via runoff. In some areas with high soil P, the recommendation is to apply manures on the basis of P needs. Such a philosophy will greatly limit applications in fields that are close to confined animals. It will also require N application and possibly other fertilizer nutrients from commercial fertilizers for balanced fertilization of most crops.

One attempt to provide more uniform applications and products that are more environmentally friendly to transport is to compost or pelletize manures. Such operations concentrate the manure and reduce transportation costs. Many composting processes have been developed. The economics are favorable for some specialty plants but not for broad-scale crop production.

Table 1 The concentrations of N, P, and K on a dry weight basis in commonly applied wastes.

Waste	N	P	K	References
Livestock manures	1–3%	0.4–2.0%	1–2.5%	[1,2]
Poultry manures	3–5%	1–3%	1–2%	[1,2]
Plant residues	1–7%	0.1–1.7%	0.1–9%	[1]
Municipal biosolids	2–9%	1.5–5%	0.2–0.8%	[3]
Municipal effluents	1.6–2.7 mg L ⁻¹	0.2–1.2 mg L ⁻¹	1.1–1.7 mg L ⁻¹	[4,5]

Other Animal Residues

Bonemeal, dried blood, and other animal processing wastes are important fertilizers but account for little of the total fertilizer used in the United States. Bonemeal is a good source of P, often used by the homeowner but seldom used in commercial agriculture. Dried blood is a rapid releasing organic N source. Other animal wastes are variable in composition and are often considered as disposal problems rather than desirable fertilizers. Applications may be difficult due to poor and non-uniform physical characteristics. Chemical analysis should be known before application.

PLANT RESIDUES

Leaving plant residues on the soil surface provides both nutrients for a following crop and soil protection from wind and rain erosion. Plant residue fertilization may also be obtained from the application of wastes or by-products from many agricultural processing plants. Trash from cotton gins, filter mud from sugarcane, and processing wastes from fruits and vegetables are but a few of the plant residues utilized. Soil conservationists have long recommended keeping the soil protected by maintaining cover crops during the seasons when the main crops are not planted and returning those plant residues to the soil. The modern emphasis on conservation tillage includes planting directly into cover crops. If the cover crop is a legume, N may be supplied to the planted crop due to the nitrogen gas fixation from the legume. A good stand of alfalfa, clover, bird's-foot trefoil, or vetch plowed into the soil may replace a fertilizer N application of 80–125 kg N ha⁻¹ for a following crop of corn.^[6,7] It is believed that such cover crops used in conservation tillage and not incorporated would supply nearly as much N to the following crop.

MUNICIPAL WASTES

Sewage treatment plants produce fertilizers in the forms of effluent (the liquid portion) and as biosolids that are settled from the effluent. In some cases, biosolids are placed in a landfill, but costs of maintaining and monitoring seepage from landfills is making the economics favor transportation and land application. Proper handling in the treatment plant removes most human and animal health concerns, but not the stigma of such applications.

Effluents

Ammonium and nitrate N should be monitored to avoid overapplication of effluents, as N leaching can be a problem in sandy soils. When application is made year-around, it is necessary to keep the soil covered with an actively

growing crop to minimize leaching.^[8] P fixation capacity of the soil is an important determinant of the amount of effluent that should be applied without promoting a soluble-P problem. High fixing soils will handle greater amounts of P than soils with little fixing capacity.^[9] Heavy metals are not a problem, as they are concentrated in the solids. N, P, and potassium (K) concentrations of effluents vary quite widely (Table 1).

Biosolids

Because of advances in technology, treatment plants are able to remove nearly all heavy metals and bacteria, allowing the nutrient-rich organic material by-products or biosolids to be recycled and applied as fertilizer. Elemental concentrations in biosolids from different sources have extremely wide variances (Table 1). They are generally good sources of both N and P for crops, but as for most manures, P application will be too great if enough is applied to satisfy N requirements. Application according to P requirements will allow little or no use in many cases.

OTHER BY-PRODUCTS AND WASTES

Many other organic by-products and wastes may be suitable and even valuable as fertilizers. Included would be paper and pulp, vegetable and fruit processing by-products, food wastes, etc.—the list is too extensive to be included here. All wastes should be analyzed for nutrient elements and for potential pollutants prior to application.

Fertilizers: Types and Formulations

Douglas Robert McGuffog

McGuffog & Co Pty Ltd, Noosa Heads, Queensland, Australia

Abstract

Fertilizer products are applied in crops, pastures, horticulture, ornamental plants, and turf to provide nutrients that are essential for plant growth. The choice of product will depend upon a number of factors including the nutrient status of the soil and the plant's requirements. A range of basic fertilizer types are produced as solids, liquids, or gas in large-scale chemical manufacturing plants or from mining processes. Urea, containing 46% nitrogen (N); diammonium phosphate, containing 18% N and 20% phosphorus (P); and potassium chloride, containing 50% potassium (K), are the most widely used products and are usually applied in solid granular form. The use of fluid forms of fertilizers is increasing in large scale intensely farmed areas in a number of countries. Ammonium polyphosphates, containing 10–11% N and 15–16% P; urea ammonium nitrate, containing 28–32% N; and potassium chloride are the most widely used components in the production of fluid fertilizers. Both solid and fluid fertilizers may be blended or mixed, and in the case of solid products compounded or coated, to provide a wide range of formulations to suit particular nutrient requirements and method of application. Secondary nutrients (calcium, magnesium, and sulfur) and micronutrients (boron, chlorine, copper, iron, manganese, molybdenum, and zinc) are usually incorporated with the primary nutrients (N, P, and K) in blends, mixtures, or compounds. Animal manures are an important source of plant nutrients in a number of countries.

INTRODUCTION

Mineral fertilizers provide essential plant nutrients for application to crops, pastures, horticulture, ornamental plants, and turf. There is a wide range of fertilizer types and formulations available that enable users to match a fertilizer to suit specific soil and plant requirements and method of application.

Fertilizers are classified by their plant nutrient content. Nitrogen (N), phosphorus (P), and potassium (K) are referred to as primary nutrients; calcium (Ca), magnesium (Mg), and sulfur (S) as secondary nutrients; and boron, chlorine, copper, iron, manganese, molybdenum, and zinc as micronutrients. Selenium is a micronutrient that is not required by plants but is important for grazing animals.

Table 1 shows the primary and secondary nutrient contents of the most commonly used fertilizers.

Animal manures are also an important source of plant nutrients in many countries and have the benefit of returning organic matter to the soil which in turn improves moisture retention.

The nutrient requirements for crop or pasture production will depend upon a number of factors such as the fertility status of the soil, the crop requirements, and the nutrient uptake pattern of the plant. This entry provides a brief overview of the major mineral fertilizer types and how they are formulated as mixtures, blends, and compounds to suit the particular application need.

TYPES OF FERTILIZER PRODUCTS

Fertilizers are produced as solids, liquids, and gas.

Most fertilizers are applied as a solid material, usually in a granular form. Fluid fertilizers (liquids) are applied as suspensions or solutions in a number of countries. In some countries, ammonia is applied directly to the soil.

Government regulations require the labeling of fertilizers with their plant nutrient content usually known as the guaranteed analysis.^[1] The N, secondary nutrient, and micronutrient contents are normally expressed as a percentage by weight of the mineral element. The P and K contents are expressed either as percentage of the element or of the oxide form, depending on individual country regulations. The typical analyses of commonly used fertilizers, expressed as a percentage by weight in both the elemental and oxide forms for the P and K contents, are shown in Table 1.^[1,2]

Gaseous Fertilizers

Anhydrous ammonia is a liquefied gas that is transported, stored, and applied under pressure. It is mostly used as a preplant fertilizer during crop fallows and is drilled directly into the soil.

Fluid Fertilizers

These are major forms of fertilizer usage in the United States, particularly for applications of N, and their use is

Table 1 Typical analyses of commonly used fertilizers.

growing in other parts of the world.^[1] There are two types: solutions and suspensions.

Solutions

All the ingredients are completely dissolved in water.

Urea ammonium nitrate (UAN) is the most commonly used N solution. It is manufactured by mixing hot solutions of urea and ammonium nitrate.^[1]

Ammonium polyphosphates are the major source of P for solutions. They are manufactured by reacting wet process superphosphoric acid containing 30–31% P (68–70% phosphorus pentoxide (P₂O₅)), ammonia, and water.^[1]

Solutions can be applied on their own or as mixtures and with added K, normally as potassium chloride. Fertilizer solutions may also be applied in low concentrations through irrigation water or as foliar sprays.^[2] Potassium nitrate is commonly used in foliar fertilizer sprays.

Suspensions

More concentrated fluid fertilizers can be prepared if insoluble or less soluble components can be held in suspension. This is particularly important for mixtures containing K and when micronutrients are required in the mixture. Insecticides, fungicides, and herbicides can also be incorporated as suspensions.

Ammonium polyphosphates are widely used in suspensions, but cheaper phosphate fertilizers such as monoammonium phosphate (MAP), diammonium phosphate (DAP), and merchant grade phosphoric acid containing 24% P (54% P₂O₅) may also be used as sources of P.^[1]

The N content of a suspension may be sourced from ammonium polyphosphates, UAN solutions, and anhydrous ammonia. The K source is normally potassium chloride. Micronutrients can be dispersed with greater uniformity in suspensions compared to dry blends.

Suspensions are typically formulated in blending vessels fitted with high-speed agitators to disperse finely divided, insoluble or partially soluble fertilizers in a liquid fertilizer solution. Suspending agents such as clays or xanthan gums are used to assist in maintaining the solids in suspension.^[3]

Suspensions will settle out if not agitated and must be used soon after formulation. Their use is largely confined to markets where there is a high demand in a relatively concentrated cropping area.

Solid Fertilizers

The majority of fertilizers are purchased and used as solid products. Products referred to as a “straight” fertilizer contain only one primary nutrient. A “compound” fertilizer contains two or more primary nutrients obtained chemically or by blending or both. Fertilizers containing two or more primary nutrients may be referred to as a blended fertilizer; complex fertilizer; mixed fertilizer; and N, P, and K fertilizer.^[1]

N Fertilizers

Urea is the world’s most commonly traded and used N fertilizer.^[4] It is manufactured by reacting ammonia and carbon dioxide at high temperatures and pressures^[5] and is produced as either a granule or a prill. It has good storage

and handling characteristics and is compatible in blends with most other commonly used fertilizers but is not compatible with superphosphates or in dry blends with ammonium nitrate.^[6]

Ammonium nitrate is the most popular form of N fertilizer in most European countries.^[1] It is manufactured by reacting nitric acid and ammonia.^[5] It is a strong oxidizing agent and may explode under certain conditions. Because of its hazardous properties, it is subject to a range of transport and storage regulations and its application as a straight fertilizer is prohibited in some countries.^[1]

Calcium ammonium nitrate (CAN) is used as a substitute for ammonium nitrate. It is manufactured by mixing a concentrated ammonium nitrate solution with a Ca source such as limestone.^[1]

Ammonium sulfate (sulfate of ammonia) is mainly sourced as a by-product from industry. It is also produced in granulation plants from sulfuric acid and ammonia.^[1] In addition to N, it contains 24% S in the sulfate form, which is readily available for plant root uptake.

P Fertilizers

DAP is the most commonly traded and used P fertilizer.^[4]

MAP is often used in preference to DAP in crops where the planting fertilizer and seed are placed together in the soil, through the same delivery hose behind a tine. Seedling injury is seldom observed with MAP.^[7]

DAP and MAP are produced in granulation plants by reacting ammonia and phosphoric acid.^[5]

Triple superphosphate is a commonly used P fertilizer in crops. It is produced by reacting phosphoric acid with phosphate rock.^[5]

Single superphosphate is used mainly as a pasture fertilizer. It contains 11–12% S in the sulfate form. It is produced by reacting sulfuric acid with phosphate rock.^[5]

K Fertilizers

Potassium chloride (muriate of potash) is the most commonly used K fertilizer.^[4] It is mined mainly from deposits of sylvinite and sylvite and then refined to fertilizer by crystallization or floatation processes.^[1] The other source is from brines in lakes or inland seas. It cannot be used on certain chloride-sensitive crops.^[2]

Potassium sulfate (sulfate of potash) is used in place of potassium chloride on chloride-sensitive crops. It is usually produced from brines.^[1]

Potassium nitrate is produced from an ore containing sodium nitrate, potassium nitrate, chlorides, and sulfates or from the reaction of potassium chloride with nitric acid.^[1] It is usually the preferred source of K in foliar sprays.

Potassium magnesium sulfate (sulfate of potash magnesia) is used where both Mg and S are required and for use on chloride-sensitive crops. It is produced from the mineral langbeinite.^[2]

Solid fertilizer compounds and blends

For many users, a manufactured compound fertilizer or a blend of two or more fertilizer products is the most cost-effective means of applying a combination of nutrients in ratios matched to the requirements of the soil and crop.

Compound Fertilizer

These are produced by one of the three major processes.

Chemical reaction—This is based on the granulation of solid raw materials such as ammonium sulfate, ammonium phosphate, and potash with liquid phase materials involving a chemical reaction between the components. The liquid phase is typically introduced from the reaction of ammonia with phosphoric acid in a process prior to introduction to the granulator. Granules are formed by agglomeration and the granules are subsequently dried.^[1]

Steam/water granulation—Solid and relatively finely divided raw materials are premixed and introduced into a granulator where steam and water are added. This results in the agglomeration of the various components into granules which are subsequently dried.^[1]

Compaction—Finely divided raw materials are preblended and mechanically agglomerated by high pressure into thin sheets of dried material on a revolving drum. The sheets are subsequently crushed to the desired particle size.^[1]

Secondary Nutrients and Micronutrients

The incorporation of secondary and micronutrients can be achieved by incorporating the nutrient sources in the solid phase prior to granulation or by coating them on the surface of a granular fertilizer. Secondary nutrients can also be introduced through choice of raw materials containing both primary and secondary nutrients, e.g., using ammonium sulfate as a source of both N and S.

A number of coating technologies are in commercial use that enable micronutrients and other additives to be evenly dispersed over the surface of granular fertilizers.

Slow and Controlled Release Fertilizers

The principal process for manufacture of controlled release fertilizer is by coating conventional soluble granules or prills with a protective coating or encapsulation.^[8] They are mainly used in high-value horticulture, in ornamentals, and on sporting ground turf.

Blended Fertilizers

These are a mixture or blend of fertilizers prepared without a chemical reaction from components that retain their physical form. They are usually prepared shortly before use and

supplied to users in bulk. DAP and potassium chloride are widely used in blends.

To achieve a uniform distribution of nutrients throughout the blend, it is essential for the components to be compatible and to be closely matched in size range and in size distribution.^[1]

Fertilizers absorb moisture causing caking and agglomeration of the particles. A mixture of two products will absorb moisture more readily than either of the individual products alone. This phenomenon and other aspects of the physical quality of a fertilizer such as moisture content and the presence of impurities and fine particles (fines) may limit the compatibility of blending materials.^[6] Absorption of moisture increases if the product components have a high content of fines.

Bulk dry blends will tend to segregate during transfer and handling operations. The degree of segregation will depend on the size and shape of the individual blending ingredients. The smaller particles will tend to move downward through the product while being transferred by conveyors or as a result of vibration when transported in bulk or bags.

Secondary nutrients such as Ca, Mg, and S can be introduced into the blend by choosing a blending ingredient containing the nutrient, e.g., Mg and S can be supplied by choosing potassium magnesium sulfate as the K source.

It is much more difficult to achieve an even distribution of micronutrients in dry blended fertilizers because of the much smaller amounts required. To overcome these limitations, it is often necessary to use micronutrients that have been bulked up with fillers and granulated.

CONCLUSION

The availability of the major fertilizer types has changed little in the past 50–60 years. Most of the innovative changes have occurred in production techniques, in the development of fluid forms of fertilizer, and in the range of different fertilizer formulations.

Reducing the environmental impact of fertilizers by the precise application of nutrients required and reduction of

nutrient losses from the point of application will become increasingly important as agricultural production intensifies. These factors will significantly influence the development of fertilizer types and formulations.

Abstract

Environmental quality is a major issue in many parts of the world and includes important topics such as sustainability and environmental protection. Sustainability and environmental protection often overlap and cover issues such as soil conservation, careful use of finite resources such as inorganic fertilizers, and the responsible recycling of urban wastes and animal manures by agriculture. The beneficial reuse of urban wastes and by-products, e.g., sewage sludge (biosolids), has become an increasingly important issue to attain sustainability as the world's population increases. This entry describes the uses of urban wastes and biosolids as fertilizers primarily for agricultural settings and the major trends, issues, options, and regulations involved. The main focus is on biosolids, as they constitute the largest portion of urban wastes that are land applied.

TYPES OF URBAN WASTES THAT ARE USED AS FERTILIZERS

Legislation in most countries requires treatment of wastewater from combined residential, commercial, and industrial sources. Treatment of wastewater produces a semisolid by-product that is commonly known as “sewage sludge” or “biosolids.” There are several disposal pathways for biosolids including incineration, landfilling, and application to land as a fertilizer. Use of biosolids in agriculture is a well-established and regulated process in many parts of the world, including the United States and Europe. To a lesser extent, other urban and industrial by-products, e.g., paper waste, and municipal solid waste (MSW), such as leaves, grass clippings, or other organic materials, are also applied to agricultural land, often following composting. Sometimes biosolids can be cocomposted with industrial by-products or MSW.

PRODUCTION OF URBAN WASTES USED AS FERTILIZER

Biosolids Production and Quality

There are several treatment processes that are routinely carried out in wastewater treatment plants. These determine the quality and properties of the biosolids produced, which in turn affects the options for land application. Following initial screening, wastewater can undergo primary, secondary, and tertiary treatments (Table 1). The treatment

used at any particular wastewater treatment plant depends on the effluent discharge limits [e.g., biological oxygen demand (BOD) or nutrient content of the treated wastewater to be discharged into surface waters] and the proposed use for the biosolids and resources available. In addition to these wastewater treatment processes, de-watering of biosolids is frequently used to reduce biosolids volume, which can in turn reduce transportation and disposal costs.

Composting of Biosolids and MSW

Composting (often called cocomposting when two or more materials are composted together) is the decomposition of organic matter by microorganisms in a controlled environment that has optimum moisture and oxygen contents. The increase in temperature during composting can destroy most pathogens. Composting of biosolids or the organic fraction of MSW may cause offensive odors and odor control systems, such as scrubbers and biofilters, are usually required in populated areas. Composting of biosolids involves mixing de-watered biosolids with a bulking agent, such as MSW, wood chips, or straw, followed by aerobic decomposition. Only a small proportion of biosolids and MSW are composted worldwide, but in certain areas composting accounts for a large proportion of the urban wastes generated. For example, Edmonton, Canada, is able to divert 70% of its residential waste from landfill using recycling and cocomposting.^[1] Where the organic fraction of MSW is composted, it can either be source separated by the

Table 1 Wastewater treatment processes.

Treatment name	Treatment process
Screening and grit removal	Generally, a combination of sedimentation and passing through a large screen to remove stones, grit, and any large debris, such as branches, that may have entered the sewage system. The product of this process is nearly always regarded as a solid waste rather than biosolids and is usually landfilled
Primary	Follows screening and grit removal and usually involves sedimentation to remove suspended solids prior to secondary treatment
Secondary	Normally, a biological treatment in which micro-organisms are used to reduce suspended solids and BOD, thereby eliminating fish kills when the wastewater is discharged. This is the minimum wastewater treatment process required in the United States
Tertiary	Used where higher standards are required for effluent quality or to improve biosolids quality for land application. Examples include addition of lime for pathogen and odor control, iron or aluminum salts for precipitation of P, and polymers for removal of suspended sediments

resident or screened and separated from regular residential garbage, and composted alone or mixed with biosolids before being composted.

REGULATIONS COVERING LAND APPLICATION OF URBAN WASTES

Land application of biosolids normally depends on the wastewater treatment process used to produce the biosolids. As specific rules vary between countries, it is impossible to describe about all of them in this entry.^[2,3] However, it is possible to make some generalizations about land application of biosolids. For example, secondary and/or tertiary treatment, mainly to control pathogens and odors, is normally required before land application is permitted.

In United States, biosolids applications are governed by Title 40 of the Code of Federal Regulations, Part 503, commonly referred to as the “503 rule,” which sets limits for toxic metals in biosolids and for both annual and cumulative loadings to land (Table 2). Limits for chromium and molybdenum are under consideration. The 503 rule also classifies biosolids as either “Class A” or “Class B” for pathogen control. The content of polychlorinated biphenyls in biosolids to be land applied is limited to a maximum of 50 mg/kg, under Title 40 of the Code of Federal Regulations, Part 761. Similar rules are in effect in the European Community, under Council Directive 86/278/EEC, implemented in 1986 and under revision.

Table 2 Pollutant limits set by the 503 rule for toxic metals in biosolids applications to land.

Pollutant	Ceiling concentration limits for all biosolids applied to land ^a (mg/kg)	Cumulative pollutant loading rate limits (kg/ha)	Annual pollutant loading rate limits (kg/ha/yr)
Arsenic	75	41	2
Cadmium	85	39	1.9
Copper	4300	1500	75
Lead	840	300	15
Mercury	57	17	0.85
Nickel	420	420	21
Selenium	100	100	5
Zinc	7500	2800	140

^aMaximum concentration of pollutant permitted in any biosolids to be land applied.

AGRICULTURAL MANAGEMENT OF URBAN WASTES AS FERTILIZERS

The benefits of biosolids and compost applications to soil quality are many and well documented. Biosolids and composts are good sources of nitrogen (N), phosphorus (P), and potassium (K). Typical biosolids contain 4.0%, 2.0%, and 0.4% of N, P, and K, respectively, on a dry weight basis, while the equivalent values for MSWs are 0.7%, 0.2%, and 0.3%, respectively. Composted biosolids contain less total N than uncomposted biosolids, owing to the addition of other materials to aid composting and loss of ammonia during the composting process. The N in composted biosolids is released more slowly, which decreases nitrate leaching. Thus, the N is available to plants over a longer period, which is more consistent with crop N uptake patterns.^[2] Biosolids and composts can also be good sources of Ca, Mg, and S, and of the micronutrients such as Fe, Cu, B, Zn, Mn, and Mo. Biosolids and composts can promote beneficial microbial activity and diversity that suppress plant diseases and the need for costly pesticides. Biosolids and composts can also improve water infiltration, water retention, and soil structure, which in turn increases resistance to wind and water erosion. In United States, in 1998, land application of biosolids accounted for 41% of the total produced, while advanced treatments such as composting accounted for 12%.^[2] The annual production of biosolids (7 million Mg/yr) is small in comparison with animal manure production (174 million Mg/yr) in United States. However, the land application of biosolids constitutes a significant economic saving for many biosolids producers and saves landfill space, which is an increasingly expensive, finite resource in many areas.

POTENTIAL PROBLEMS ASSOCIATED WITH LAND APPLICATION OF BIOSOLIDS

Legitimate concerns about the need to prevent toxic metals and pathogens from affecting human and ecosystem health have been addressed through regulation and record keeping of applications of biosolids to land. However, there is a debate as to whether the limits set for toxic metals and pathogens are strict enough. Some scientists think that metal bioavailability will increase as the organic matter added with the biosolids is mineralized, while others argue that the evidence to support this hypothesis is inconclusive.

Biosolids and composts have a low N/P ratio compared to crop requirements. Biosolids applications are generally carried out according to N-based nutrient management plans that over-apply P and can lead to a buildup of P in agricultural soils.^[4] Buildup of soil P in many areas has been linked to increase in losses of P from agriculture to surface waters, with a corresponding decrease in water quality. Biosolids may have to be applied according to P-based nutrient management plans. This will decrease the amount of biosolids that can be applied per unit area of land, introduce the necessity for inorganic N fertilizers, and increase other associated costs. Nuisance issues such as odors and attraction of pests are of public concern when application sites are close to residential areas.^[5]

CONCLUSION

Efforts to recycle municipal wastes will likely continue, driven by human population growth, the continuing rise in cost of landfill, and the goal of sustainability in agriculture and the environment as a whole. However, the land-application programs for biosolids are uncertain. For

example, the USEPA has forecast an increase in the beneficial use of biosolids in land-application programs because of increasing costs associated with landfill and an increase in biosolids quality owing to stricter regulations covering biosolids production. Despite increasing biosolids quality, the argument over the long-term environmental impact of pollutants in biosolids will likely continue. Further regulation of the application of P to agricultural land may also increase costs associated with land-application programs for biosolids and municipal wastes. However, if the potential negative side effects associated with the land application of biosolids and composted waste are properly managed, then the beneficial use of these by-products will continue.

Abstract

Natural or man-made vegetation fires lead to major changes in soil properties and nutrient cycling processes. Through their direct and indirect effects, fires can significantly impact on land productivity, plant diversity, and greenhouse gas emissions. The level of fire impact is highly dependent on the fire regime (intensity, frequency, and season of burn), soil type (especially erodibility), and postfire weather conditions. Fire impacts nutrient cycling in ecosystems via the effects of soil heating, ash additions, altered microclimate, and changed vegetation dynamics. Key mechanisms are: 1) direct or indirect losses of nutrients during and after fires; 2) transformation of some nutrients from organic into inorganic forms; 3) heating of the soil which initiates a number of chemical and biotic processes affecting decomposer activity and nutrient uptake by vegetation; 4) changed vegetation composition, structure, and growth rate, and thus the uptake and turnover of nutrients; 5) changed chemical environment of plant roots (pH, exchangeable cations, soil solution composition, solubility, and composition of minerals); 6) changed hydrology and temperature regimes which affect other soil processes; and 7) changes in vegetation succession (e.g., stimulation of nitrogen-fixing understory vegetation).

INTRODUCTION

Fires have played an integral role in the evolution and ecology of many ecosystems of the world. Natural and managed fires burn extensive areas annually and shape the landscape through effects on vegetation, soil, water, biodiversity, and socioeconomics. Fire has been actively managed for human benefit for millennia. In the tropics, slash-and-burn agriculture uses fire to release many of the nutrients accumulated in vegetation during a fallow period. Similarly, fire is widely used to remove forest and agricultural residues prior to establishment of a new crop or to enhance grazing.

Fire is a dominant driver of the historical and vegetation dynamics in forests, woodlands, shrublands, and grasslands in many parts of the world. Fire management practices (suppression, prescribed burning, etc.) remain controversial in many parts of the world because they can affect soil and a range of other factors with environmental values, including greenhouse gas (GHG) emissions [carbon dioxide (CO₂), carbon monoxide (CO), methane (CH₄), and nitrogen dioxide (NO₂)] and air quality.

FIRE REGIMES AND FIRE IMPACTS ON SOILS

Fire can affect soil properties and processes both directly, as a result of combustion (via nutrient transfers to the

atmosphere, ash and char inputs, and soil heating), and subsequently as a result of a myriad of changes to ecosystem processes such as changed mineralization rates of soil organic matter and litter, erosion of ash and nutrient-rich surface soil, vegetation succession, and changes to nitrogen (N)-fixing systems.^[1–3] The scale of change ranges from minutes (soil heating) to many decades (vegetation succession), with the postfire impacts on soils often being the most dominant.

Intensity and frequency of fires are major factors affecting the change in soils. The type and quantity of fuel consumed, and thus the duration of soil heating can be used to categorize fires in terms of impacts on soil and ecosystem processes (Table 1).

ATMOSPHERIC LOSSES OF ELEMENTS

During vegetation fires, atmospheric losses of elements occur in non-particulate [e.g., carbon (C), N, sulfur (S), and phosphorus (P)] and particulate forms [calcium (Ca), magnesium (Mg), potassium (K), and P], and postfire residues (partially burnt fuels, ash, and char components) are deposited on the soil. Depending upon the degree of combustion, a range of GHG gases are formed, the most important ones being CO₂, CO, nitrous oxide (N₂O), and CH₄.

Elements undergoing non-particulate (gaseous) losses would undergo a long-range transport in the atmosphere

Table 1 Fire categories as defined by fuel type, fuel quantity, and the duration of soil heating.

Fire category	Fuel types	Fuel consumption (t/ha)	Maximum temperature (°C) at 2-cm depth	Time (hr) for which soil is heated above 80% of the maximum temperature	Frequency of occurrence (yr)	Relative impact on soils
Windrows	Mostly trunks and slash	100–400+	500	>24	30–100+	High
Forest regeneration/slash	Tree crowns, some logs, shrubs, and litter	50–300+	200	0.5–2	30–100+	High
Forest wildfire	Litter, shrubs, and crowns	20–60	100	0.1–1	20–100+	Medium to high
Shrubland	Litter and crowns	15–30	80	0.1–0.5	20+	Medium to low
Grassland, crop residue	Litter, crop residues	0.5–5.0	60	0.1–0.3	1+	Low

Note: Values are a guide, with considerable variation observed.

Source: From Walker, Raison, et al.^[6]

(considered to be a complete loss to ecosystems), whereas particulates may be carried for only shorter distances. Raison, Khanna, and Woods^[4] used the conservation of Ca to distinguish between particulate and non-particulate losses of different elements and reported that a direct correlation existed, providing the possibility of estimating accurately the loss of N from N content of the fuel and the amount of dry matter burnt. Up to 60% of P contained in the fuel may be lost, depending on factors such as the temperature, forms of P in the fuel, cation content of the ash, and the amount of ash transport. The non-particulate transfer of P may range from 30% (low combustion) to 50% (high combustion). When combustion is relatively complete (gray ash is produced), non-particulate losses of many elements may account for 60–80% of the total atmospheric transfer.^[4]

EFFECTS OF SOIL HEATING

Less than 10% of the heat produced during a vegetation fire is radiated downward, yet this heating is responsible for much of the direct changes in soil properties caused by forest fire.^[5] The direct effects of heating on organic matter and soils range from mild sterilization and denaturing of protein at 50–60°C to changes to clay minerals at 950°C.^[6] Depending upon the degree of oxidation, carbonized products are produced, which range from mineral gray ash containing very little residual C to black residue with a high amount of C and charred substances. Moderate heating can render soil organic matter more prone to microbial respiration under postfire conditions.^[6] Soil heating may be as important as the addition of ash in slash-and-burn systems and can increase mineral N and P fractions.^[7]

EFFECTS OF ASH ADDITIONS

After fire, postfire residues deposit highly aromatic (char) C. About 1–5% of burnt fuel is converted to char, and this is

considered to be relatively inert and likely to be long-lived in soils^[8] and sediments.^[3]

Elements, except C and N, are enriched when ash is formed, with the level of their enrichment dependent on the degree of combustion and initial fuel characteristics. In comparison with unburnt eucalypt fuels, concentrations of Ca, Mg, and P increased by 10- to 50-fold, 10- to 35-fold, and 10-fold, respectively,^[9] with high values in gray ash. As ash is prone to be transported by wind and water, any loss of ash can cause major losses of elements from ecosystems. Ash is highly alkaline and will increase the pH of the soil and its capacity to buffer protons. The salt content of ash may initially inhibit seedling growth, but plants growing around an ashbed benefit from the nutrients made available in the short and long term, causing the so-called “ashbed effect.” Ash can also stimulate soil biological activity^[10] and interact positively with the effects of soil heating.^[2,6]

CHANGES IN SOIL PHYSICAL PROCESSES

Fire affects water penetration and erosion susceptibility by creating hydrophobicity^[11] in the surface soil. Erosion has major effects on soil fertility. Blackening of the soil surface and removal of vegetation and litter can increase soil temperature. Where fire reduces the vegetation cover, frost damage may increase, plant water uptake is reduced, thereby increasing the soil wetness, and, sometimes, rates of mineralization of soil organic matter and leaching of nutrients.

CHANGES IN SOIL CHEMICAL PROPERTIES AND PROCESSES

Large quantities of cations (Ca, Mg, K, and ammonium (NH₄)), anions (chlorine (Cl) and sulfate (SO₄)), and soluble silica are mobilized in surface soils by vegetation fire, especially under ashbeds^[12] where Ca remained the main

cation in the solution phase of surface soil during a 3-year study period. Increase in exchange capacity (because of the pH change in acid soils) and the exchangeable base cations occurs after fire and may remain so for many years after intense fire. Nitrification rates and hence the potential for leaching of nitrate and cations may be increased after intense fire.^[1,3,13] A small fraction (about 10%) of total P in ash may be soluble in water.^[10] Protons are needed to mobilize P deposited in ash and, therefore, mixing of ash with acid soil is required before P can be used by postburn vegetation. The P-sorption capacity of soils usually increases after intense forest fire.

CHANGES IN BIOLOGICAL PROPERTIES OF SOILS

The effects of fire on biological processes are complex and can be very site dependent. Fire often enhances the decomposition of organic matter and the mineralization of organically bound elements. This can be because of the changed microbial populations, altered substrate quality (additional soluble C), and more favorable environmental factors (temperature, moisture, and pH). For example, in laboratory experiments where ash was added to different soils, enhanced respiration rates, especially in soils with high organic matter content, were observed during 6 weeks of incubation^[10] until the easily mineralizable soil C was respired.^[13] N mineralization rates and the amount of nitrate produced usually increase following a fire, and in some cases may lead to loss of N by denitrification.^[10] A change in microbial population (autotrophic nitrifiers replacing heterotrophic nitrifiers) after fire has been proposed by Bauhus, Khanna, and Raison.^[13] Study of denitrification rates after fire deserves greater research attention.

CHANGES IN NUTRIENT CYCLING

Selection of appropriate soil parameters is needed for successful study of the impacts of fire on nutrient cycling. Often the selected soil parameters are either insensitive to small changes which may be caused by fire or studies are not of sufficient duration. The objective in most studies should be to ensure that the active biological sites and labile nutrient fractions in surface soils are adequately sampled. Care must be taken to avoid treatments to field soils prior to analysis that could mask the effects of fire that are occurring in the field. For example, disturbed (mixed or dried) soil samples are moistened to a fixed level and incubated at a fixed temperature regime to study the effects of fire on N mineralization, the results may be very different to those taking place *in situ*.^[14]

For forest ecosystems, fire may pose a significant risk to the maintenance of nutrient cycles in the following circumstances:^[15]

1. Where forests are already nutrient limited and where natural inputs of nutrients, especially of N and P, are small.
2. Where a high proportion of site nutrient pools are held in combustible vegetation or dead organic matter.
3. Where fuel mass (and fuel nutrient content) reaccumulates rapidly after burning, and there is frequent fire. Where fire intensity and the mass of fuel combusted are high.
4. Where fire induces increases in erosion of ash and/or surface soil (typically when there are erodible soils, steep slopes, and high rain intensities).
5. Where fire reduces rates of N fixation (e.g., by changing the composition of understory vegetation).
6. Where the frequency of fire is increased compared to historical rates due to climate change, population pressure, or changed fire management policies.

MANAGEMENT OF SOILS FOLLOWING FIRE

One of the immediate concerns following vegetation fires is minimizing soil erosion and replenishing nutrients that are lost by atmospheric transfer or erosion. Losses of N can be large (several hundred kg/ha) in forests that are subjected to wildfires or slash burns. In natural systems, given sufficient time, N-fixing processes can maintain N balance. Replenishment of lost P and cations may take decades or centuries, so that plant productivity can be reduced if such fires occur too frequently. In managed systems, fertilizer inputs may be needed to maintain productivity.

Fluid Flow: Modeling

John L. Nieber

*Department of Biosystems and Agricultural Engineering, University of Minnesota,
St. Paul, Minnesota, U.S.A.*

Abstract

The unsaturated zone (vadose zone) of the earth's crust is an important interface for both the underlying groundwater and the overlying surface water resources and atmosphere. Quantifying fluid flow, mass transport, and energy transport processes in the unsaturated zone have become a focus for researchers, government agencies, and consultants because it is found that the outcomes of these processes have an impact on the sustainability of modern social structures. While sophisticated sensors and instrumentation seem to have been developed to provide data from the field on a real-time basis, these cannot be used to directly predict the possible outcomes. Instead, this prediction requires the use of mathematical models representing the flow and transport processes. The following describes some of the applications of models for flow in the unsaturated zone, past challenges and achievements in improving modeling methods, and future challenges to modeling flow.

APPLICATION OF MODELS

Models for simulating flow processes in soil and groundwater find applications in many environmentally oriented disciplines including geography, soil science, agricultural engineering, civil engineering, geoengineering, hydrogeology, and meteorology. These models are generally based on numerical solutions of governing equations and require the use of digital computers to complete the calculation task. There are many potential applications for such models, but a short list of the common applications includes the following: 1) the estimation of groundwater recharge volume and contaminant loading; 2) the design of measures to remediate contaminated soils and groundwater; 3) the design of efficient drainage and irrigation systems for efficient crop production; 4) the estimation of runoff production from land in response to rainfall and/or snowmelt; and 5) the assessment of the impact of global climate change on surface and subsurface water resources.

Models developed for these applications need to satisfy two criteria to be put to use by a practitioner. They have to be fairly easy to use and dependable. The first criterion, ease of use, only requires a good team of programmers and does not pose a challenge for flow modeling. The second criterion stipulates that the model provides accurate results in a timely manner. This is a direct challenge to flow modeling. The following sections present information on the past and future challenges associated with the development of dependable models.

PAST CHALLENGES AND ACHIEVEMENTS

There has been substantial progress in the development of numerical models for simulating relevant unsaturated

zone processes. During this time, predominant attention in modeling flow processes was given to the Richards' equation.^[1] In the past, many of the difficulties in model development involved the determination of the best ways to solve this equation.

Due to the highly non-linear character of the Richards' equation, analytical solutions^[2] to the equation were possible only for simplified conditions, and therefore, numerical solution methods were necessary to treat realistic field conditions. Numerical methods such as the finite difference method and the finite element method were adopted from other engineering and science applications and applied to discretize the Richards' equation into the systems of non-linear algebraic equations. Two major numerical solution problems were faced by researchers in solving this equation. One was the highly non-linear nature of the equation and associated boundary conditions, leading to problems of slow convergence or even non-convergence of the solution methods. This problem was handled by applying non-linear equation solvers classified within the broad class of Newton's methods and Picard's methods.^[3]

A second problem was the need to be able to solve large systems of algebraic equations, which in earlier years involved hundreds or perhaps thousands of equations. Due to the relatively small memory available on early computers, it was necessary to use iterative methods to solve even moderate-sized problems. Conventional iterative methods such as Jacobi, Gauss-Seidel, and successive over-relaxation methods^[4] were used to solve these problems. While these methods were satisfactory for relatively homogeneous systems, for strongly heterogeneous systems, it was found that these methods led to poor convergence or even non-convergence. Computer memory did increase substantially during the 1980s and 1990s, and this allowed the use of direct equation solvers for the types of problems

solved in the earlier years. However, with the increase of computer memory storage, the problems tackled have also increased memory requirements (tens of thousands to millions of equations need to be solved), and iterative methods are once again back in vogue. Fortunately, the efficiency of iterative methods has also increased substantially with the development of conjugate gradient methods^[5] and multi-grid methods.^[6]

There has been an effort to find the recipe for a numerical method or set of methods that will be robust for solving the Richards' equation.^[3,4,7-12] The desire has been to develop computationally efficient methods applicable to a broad range of practical problems, especially for large-scale, 3-D, heterogeneous flow systems. Associated problems involved assuring that the solutions were mass conservative and that the iterative methods used to solve the non-linear algebraic equations would converge even for conditions where the soil is very dry and highly heterogeneous. The detailed analysis of how to assure a mass conservative solution has been given in the study by Rathfelder and Abriola.^[8] Assurance of non-linear iteration convergence has been found to be more problematic, and improvements have been made using techniques involving primary variable switching,^[9,10] higher-order time integration,^[11] and variable transformation.^[12]

Aside from the obvious problems associated with solving the Richards' equation, there has been the need to assign (spatially) the equation parameters for field-scale applications of the numerical solutions. For instance, the catchment scale model of Paniconi and Wood,^[13] as the model of Freeze,^[4] was developed to facilitate the simulation of 3-D variably saturated flow over an entire catchment. While the solution of the large system of algebraic equations for such a problem offers a significant challenge to modeling, an equal if not larger challenge is the problem of assigning parameters to the cells in the numerical grid.

The problem of parameter assignment is twofold. There is the problem of determining the spatial distribution of the parameters at the scale of the numerical grid cell. Involved with this problem is the uncertainty in predicting these values, given limited field data. Geostatistical methods^[14] were developed to facilitate such prediction and to estimate the limits of uncertainty. A second problem arises because small-scale features, and even small-scale processes, occurring below the sampling scale of the field-scale grid cell can significantly influence the actual outcome at the field scale but are not directly predictable by the governing equation(s) discretized at the field-scale grid. There has been some success^[15] in developing techniques that provide parameters that account for these subgrid scale features and processes. These parameters, called *effective* parameters, are those that yield *effectively* the same outcome as would occur if the more detailed parameter distribution were used.

FUTURE CHALLENGES TO MODELING

Two of the greatest future challenges to modeling include the need to more completely describe the flow and transport processes and the need to incorporate multiscale phenomena into the modeling analysis. The first challenge involves the expansion of the governing equations to include coupled physical and chemical processes. The second challenge involves the assignment of equation parameters and the incorporation of subgrid features and processes. To assure the success of future modeling, the second challenge is the most critical to address.

Governing Equations

As awareness of environmental problems has increased, and environmental regulations have become more stringent, the scope for modeling has expanded from modeling the flow of water alone to modeling coupled multiphase fluid flows, mass (solute) transport, and energy (thermal) transport. The coupled equations for isothermal multiphase fluid flow have been reviewed in detail.^[16] Numerical solutions of coupled two-phase flow equations for applications to environmental problems have advanced considerably. One of the earlier multiphase flow solutions is given in the study by Kaluarachchi and Parker,^[17] while methods representing the advances in computational efficiency are given in the study by Bastian and Helmig.^[18]

Equations for non-isothermal conditions, which have received much less attention, have been presented in the study by Nassar and Horton.^[19] The solutions of these equations offer new challenges to those developing numerical solutions.^[20,21] Techniques such as those mentioned earlier for the solution of the Richards' equation and the coupled multiphase flow equations should be tested to improve the efficiency of such solutions.

Process Scale

Numerical solutions of flow and transport processes for field-scale applications are generally performed on relatively large numerical grids. The reason for this is twofold. First, the computational effort to simulate field-scale problems can easily exceed the capabilities of the modern computers (using modern numerical methods); if too fine, a grid is used. Second, one generally does not know what values of parameters to assign to very fine grids due to inadequate spatial resolution in field data. As a result, it is necessary to assign effective parameters to the field-scale grid cells. One approach is to use stochastic methods^[15] to derive effective parameters. Renormalization methods,^[22] which rely on numerical methods, are another means to derive effective parameters.

In some instances, the governing equations may behave differently at the small scale than at the large scale. For instance, in the case of finger flow^[23,24] or funnel

flow,^[25] the flow occurs on a scale of about 10 cm. To simulate these flow features directly, it is necessary to use relatively small grid cells. Using large grid cells without considering these small-scale processes leads to a diffuse solution, and the small-scale features are missed. Effectively capturing the dynamics of these small-scale processes into a field-scale grid requires an appropriate procedure for upscaling the governing equations from the small scale to the field-grid scale. Such a procedure has been demonstrated^[26] for viscous fingering in multiphase flow and is an area of active research.

The discussion about process scale poses the question about whether the governing equations maintain a constant form in the progression from the small scale to the large scale. Addressing this question involves the principles developed in the field of multiscale science.^[27] While these developments originated in the fields of solid mechanics and fluid mechanics, they are receiving much attention in hydrology, soil physics, and hydrogeology.

Abstract

Zinc (Zn) and iron (Fe) are essential for the normal, healthy growth and reproduction of all higher plants, animals, and humans and are therefore called “essential trace elements” or “micronutrients” in plants and “micro mineral nutrients” in animals and humans. Zn and Fe deficiencies are well-documented public health issues and an important soil constraint to crop production. Generally, there is a close geographical overlap between soil deficiency and human deficiency of Zn and Fe, suggesting the need for increasing concentrations of these micronutrients in food crops. Breeding new plant genotypes for high grain concentrations of Fe and Zn (genetic biofortification) is an effective strategy to address the problem; but this strategy is a long-term process. A rapid and complementary approach is therefore required for biofortification of food crops with Zn and Fe in the short term. Agronomic biofortification/ferti-fortification using micronutrient fertilizers represents such a fast and effective strategy. Agronomic biofortification of food crops has received considerable attention globally.

INTRODUCTION

Micronutrient deficiencies in soils, plants, animals, and humans are becoming increasingly important globally. Intensive cultivation of high-yielding cultivars with heavy applications of nitrogen (N), phosphorous (P), and potassium (K) fertilizers and year after year heavy harvests without application of micronutrient fertilizers have led to micronutrient deficiencies in soils of many countries especially in high-populated Asian countries, such as India and China. The most micronutrient deficiencies reported worldwide are those of zinc (Zn) and iron (Fe). Zn as well as Fe deficiencies occur mostly in alkaline calcareous soils where chemical availability of Zn and Fe to plant roots is extremely low. It is estimated that Fe deficiency occurs in about 30% of the cultivated soils on the world and results in large decreases in crop production and quality. Zn deficiency is also widespread throughout the world and occurs in nearly all countries. Based on analysis of 298 soil samples from different countries, Zn deficiency has been found to be the most widespread micronutrient deficiency worldwide. Nearly 50% of the soils cultivated for cereal production globally have low levels of plant available Zn. In Turkey, Zn deficiency is the most widespread; the half of all cultivated soils (28 million hectares) has Zn deficiency. Zn and Fe deficiencies are prevalent, particularly in the developing world.

In many parts of the world, micronutrient deficiencies are a growing public health and socioeconomic issue and are a more widespread problem than poor dietary quality and low-energy intake, and about 20% of deaths in children under 5 years can be attributed to vitamin A, Zn, Fe, and/or

iodine deficiencies. Dietary deficiency of essential micronutrients such as Zn and Fe affects more than two billion people worldwide, especially pregnant women and children below the age of five who suffer from severe acute malnutrition.

Fe deficiency is the most common nutritional disorder in the world, and almost 1.6 billion people are suffering from its deficiency. Fe deficiency anemia results in impaired physical growth, mental development, and learning capacity. Zn deficiency is equally serious and is ranked as the 5th leading risk factor for diseases in the developing world. Numerous health problems link Zn deficiency to retarded growth, skeletal abnormalities, delayed wound healing, increased abortion risk, and diarrhea. Approximately one-third of the world's population is suffering from Zn deficiency. The situation is even more adverse in developing countries where more than half of the children and pregnant women are suffering from Fe and Zn deficiencies.

In countries with a high incidence of micronutrient deficiencies, cereal-based foods represent the largest proportion of the daily diet. The HarvestPlus initiative of the Consultative Group for International Agricultural Research (CGIAR) consortium (www.harvestplus.org) is working with national and international partners to alleviate deficiencies of these mineral nutrients by biofortifying staple food crops with essential minerals and vitamins; an approach considered to be the most economical solution to human micronutrient deficiency. The biofortification program is focusing on three micronutrients that are widely recognized by the World Health Organization as limiting. These are Fe, Zn, and vitamin A. Full-time breeding programs are under way for six staple food crops viz., rice

(*Oryza sativa*), wheat (*Triticum aestivum*), maize (*Zea mays*), cassava (*Manihot esculenta*), sweet potatoes (*Ipomoea batatas*), and common beans (*Phaseolus vulgaris*). Prebreeding feasibility studies are proposed for eleven additional staples: bananas, barley, cowpeas, groundnuts, lentils, millet, pigeon peas, plantains, potatoes, sorghum, and yams. Although plant breeding is the most sustainable solution to the problem, developing new micronutrient-rich plant genotypes is a protracted process and its effectiveness can be limited by the low amount of readily available pools of micronutrients in soil solution.

Cereal crops are inherently very low in grain Zn and Fe concentrations, and growing them on potentially Zn- and Fe-deficient soils further reduces Fe and Zn concentrations in grain. Application of Zn- and Fe-containing fertilizers (i.e., agronomic biofortification) is a rapid solution and represents a complementary approach to breeding, which needs to be taken on priority at the global level to overcome these two essential micronutrients deficiencies in the food chain.

AGRONOMIC BIOFORTIFICATION OF CEREAL GRAINS

Essentiality of Fe in plants was reported by Sachs in 1860, while that of Zn was established by Maze in 1916.^[1] Zn deficiency was later reported in citrus in the United States. A number of reviews on Zn in crop nutrition are available.^[2] In India, Zn deficiency was first reported in rice by Nene^[3] and was followed by that in wheat in Punjab. Research on Zn in relation to crop production in India has been thoroughly reviewed.^[4] However, most work on Zn fertilization was done from the viewpoint of increasing crop yield. Work on agronomic biofortification of wheat was started in Turkey by Cakmak,^[5] whereas in India, it was initiated on rice by the authors of this entry.^[6–11] Most information on biofortification of cereal grains with Zn is available on rice and wheat and is briefly reviewed.

Rice

Method of application

Zn can be applied to soil or foliage. The seed priming with Zn fertilizers and dipping of rice seedlings in Zn fertilizer solutions have also been tested and recommended for increased yield, but no data are available on their effect on biofortification of rice grains. Shivay and Prasad^[6] from New Delhi showed that on Zn-deficient soils, application of Zn as zinc sulfate heptahydrate (ZnSHH) significantly increased grain yield of rice as well as Zn concentration in rice grain.

Foliar application of only 1.2 kg Zn ha⁻¹ as compared with 5.3 kg Zn ha⁻¹ as soil application gave similar grain yield of rice, but higher Zn concentration in grain.^[12,13] Agronomic efficiency of Zn with foliar application was about 4 times of that for soil application and rate of Zn application was much lower when applied on foliage. A study from Ludhiana, India, showed that averaged on five rice cultivars foliar-applied Zn (three sprays of 0.5% ZnSHH solution) recorded a Zn concentration of 47.0 mg kg⁻¹ grain in brown rice as compared to 33.8 mg kg⁻¹ grain in no Zn check.^[14] In a multilocation study in China, India, Lao PDR, Thailand, and Turkey, Zn concentration in unhusked rice grain was about 69% higher with foliar application than with soil application; at some locations, it was almost twice that of with soil application.^[15] This study also provided data on relative Zn concentration in unhusked (whole grain with husk, known as paddy in India; most of the data on biofortification of rice are on unhusked rice), brown rice (whole caryopsis with husk removed by hand), and white rice (outer layer of pericarps is including pericarp, testa, mucella, and part of aleurone layer along with embryo removed by polishing for 30 seconds in a standard laboratory mill). White rice is also known as polished rice (the form in which rice is mostly consumed). When Zn was foliar applied, only 53–54% of that in unhusked rice was found in polished or white rice as compared with 84.8%, when Zn was soil applied (Table 1).

Table 1 Grain yield and relative zinc concentration in unhusked, brown, and white (polished) rice (averaged over nine site years in China, India, Lao PDR, Thailand, and Turkey).

Characteristic	Control (no Zn)	Soil Zn	Foliar Zn	Soil + Foliar Zn	Significance
Grain yield (t ha ⁻¹)	6.7	7.0	6.9	7.0	NS
Zn in unhusked rice (mg kg ⁻¹)	18.7	19.1	32.3	34.7	P < 0.01
Zn in brown rice (mg kg ⁻¹)	19.1	20.8	24.4	25.5	P < 0.01
	(102.1) ^a	(108.9)	(75.5)	(73.5)	
Zn in polished rice (mg kg ⁻¹)	16.1	16.2	17.7	18.4	P < 0.01
	(18.1) ^b	(84.8)	(54.8)	(53.0)	
	(84.2) ^c	(77.9)	(72.5)	(72.1)	

^aZn in brown rice expressed as percentage of unhusked rice.

Source: From Phattarakul, Rerkasem, et al.^[15] ©2012 Springer.

However, when Zn is soil applied, brown rice may contain a little more than in unhusked rice. Thus, a greater portion of foliar-applied Zn remained in husk. These data support that in rice, Zn absorbed from the root plays a major role, whereas mobilization from the leaves plays a minor role.^[16] Using the data of Phattarakul et al.^[15] as the base, it worked out that although unhusked rice contained 52.6% Zn, the polished rice from it is likely to contain only 28.8% Zn, when Zn was foliar applied in the study of Shivay and Prasad.^[6] As a contrast, when Zn was soil applied in sufficient quantity, Zn concentration in unhusked rice was 47.5%, whereas it was 40.3% in polished rice. Total Zn uptake by polished rice was also higher with soil-applied Zn; of course, much more Zn was applied to soil (25 kg ha⁻¹) as compared with that on foliage (1.2 kg ha⁻¹). Biofortification recovery efficiency ($BRE_{Zn} = 100\{[Zn \text{ concentration in polished rice (mg kg}^{-1}) \times \text{polished rice yield (t ha}^{-1}) \text{ in plus (+) Zn plots}] - [Zn \text{ concentration in polished rice (mg kg}^{-1}) - \text{polished rice yield (t ha}^{-1}) \text{ in minus (-) Zn plots}]\} \div \text{Zn applied in kg ha}^{-1}\}$), the term suggested by Impa and Johnson-Beebout,^[17] with foliar application was about eight times of that obtained with soil application. A study from Thailand reported that the decrease in Zn concentration on milling of rice ranged from 16.2% to 48.2% in rice genotypes, being more in long and slender grain types. The range of Zn (mg kg⁻¹) in polished rice was 9.6–40.2 (mean 20.6) when compared with 17.3–59.2 (mean 28.7) in brown rice.^[18]

In eastern India and in some other Asian countries, rice is parboiled before milling. Parboiling is a hydrothermal process to which unhusked rice is subjected before milling. It involves soaking in water, steaming, and drying; the degree of soaking and steaming differs considerably.^[19] As parboiled rice gives much better head rice recovery and most of the millers practiced parboiling to some degree to avoid the breakage losses. On soaking unhusked rice, nutrients from the outer layer of endosperm (pericarp, seed coat, nucellus, and aleurone layer) move into endosperm and the parboiled white rice is much richer in vitamins and minerals and has a better storage quality. Thus, the data on biofortification of rice grains depend very much on the milling process adopted. A study reported that when rice grains were soaked in Fe-ethylenediaminetetraacetic acid (EDTA) + zinc sulfate (ZnSO₄) solutions, Fe and Zn penetrated across the husk and aleurone layer into endosperm, and when parboiled, the polished rice retained 70–80.5% of Fe and Zn.^[20] Also, Fe and Zn polished rice was highly bioaccessible.

Sources of Zn

Results from New Delhi, India, reported that ZnSHH-coated urea was significantly superior to zinc oxide (ZnO)-coated urea in increasing Zn concentration in unhusked rice^[8,10–12] (also in polished rice when calculated on the basis of Phattarakul's data). The superiority of

ZnSHH was also recorded in succeeding wheat.^[8,10] Zn was applied to rice only. Water solubility of Zn sources is considered as an important criterion for Zn availability. A study from the United States reported that the effectiveness of six granulated Zn fertilizers decreased as the percent of water-soluble Zn decreased in them and calculated that at least 50% water-soluble Zn was considered desirable.^[21] In the United States, Zn fertilizer manufacturers are producing mixture of ZnSO₄ and ZnO, which are known as Zn-oxysulfates. However, from the manufacturer's point of view, ZnO is easier to coat because it forms a good emulsion with oil. Kiekens^[22] suggested that ZnO, zinc hydroxide, and zinc carbonate are about 105 times more soluble than soil Zn and these materials could be used as fertilizers.

A field study was carried out to compare ZnSHH and Zn-EDTA for rice at Pakyong, Sikkim. ZnSHH was applied at 10 and 20 kg ha⁻¹ as basal or in two equal splits (half basal and the rest half at grand tillering stage). Zn-EDTA was applied at 0.5 or 1.0 kg ha⁻¹ in single application as basal; 1 kg ha⁻¹ was also applied in two equal splits. Zn concentration in rice grain was significantly more (30.3 mg kg⁻¹) with 0.5 kg ha⁻¹ Zn-EDTA than with 10 kg ha⁻¹ ZnSHH (25.5 mg kg⁻¹). Split application was better than a single application in ZnSHH but not in Zn-EDTA. Zn-EDTA was better than ZnSHH, but more expensive.^[23]

Wheat

Soil Zn deficiency in major wheat growing areas leads to inherently low grain Zn concentration and is considered as a major factor in low human Zn intake.^[24] Soil Zn applications are less effective in increasing grain Zn concentration, while foliar Zn applications result in remarkable increases in grain Zn concentration in wheat.^[25,26] By optimizing the timing and the solute concentration of foliar Zn application, wheat grain Zn concentration could be further increased, not only in whole grains but also in the endosperm.^[26,27] Various methods of Zn application may differentially influence yield and grain Zn concentration. Knowledge of the different forms of Zn fertilizer and timing of foliar Zn application are crucial for enhancing grain Zn. The most effective method for increasing grain Zn is the soil + foliar application method, which may result in an about threefold increase in grain Zn concentration.^[25] When a high concentration of grain Zn is targeted, in addition to a high grain yield, combined soil and foliar application are recommended. Alternatively, using seeds with high Zn concentrations, together with foliar application of Zn, is also an effective way to improve both grain yield and grain Zn concentration. Applying Zn during the grain development stage contributes to increased grain Zn concentration^[27] as foliarly applied Zn can be absorbed by the leaf epidermis and then transported to other plant parts via the xylem and phloem. Field experiment results reported from Rothamsted, U.K., showed that sewage sludge application

to soil can increase Zn concentration in wheat grain in non-calcareous soils, but not in a calcareous soil for at least 2–8 years after application and was similar in effectiveness to Zn carbonate.^[28]

The timing of foliar Zn application is an important factor determining its effectiveness in increasing grain Zn concentration; large grain Zn increases are most likely when foliar Zn fertilizers are applied to plants at a late growth stage. A field study in Turkey was carried out to see the changes in grain Zn concentration in wheat during the reproductive stage and found that the highest concentration of grain Zn occurs during the milk stage of grain development. Foliar application of Zn during reproductive growth seems to be more effective in increasing grain Zn concentration than spraying of Zn at earlier growth stages. In addition to increasing the concentration of Zn in the whole grain, foliar application also increased the concentration in the starchy endosperm. Late season foliar application of Zn increased the Zn concentration in the starchy endosperm by up to threefold.^[29] Since the concentration of phytate in the starchy endosperm (i.e., white flour) of wheat is very low, or even not measurable, such an increase in Zn implies a positive effect on the use of the grain for human nutrition. The increased Zn in the starchy endosperm resulting from foliar application should also be highly bioavailable due to the low phytate content.

Among the different forms of Zn fertilizer that were tested, application of Zn as ZnSHH was most effective in increasing grain Zn, compared to other forms of Zn. The Harvest Zinc (www.harvestzinc.org) initiative has been investigating different fertilizer strategies and the most efficient Zn application method for promoting Zn uptake and maximizing grain Zn accumulation. Increasing grain Zn by soil and/or foliar applications also provides additional positive impacts in terms of seed vitality and seedling vigor. Priming seeds in Zn-containing solutions is an alternative way to increase seed Zn prior to sowing. High-seed Zn concentrations ensure good root growth and contribute to better protection against soil-borne pathogens.^[30] Preliminary studies showed that ZnSHH could be mixed with some wheat herbicides, insecticides, and fungicides without affecting the effectiveness of foliar application for increasing grain Zn concentration. This would increase the possibility that farmers may be willing to apply ZnSHH in their fields by reducing the cost and time of application (Cakmak and Ortiz-Monasterio, unpublished results). Cakmak et al.^[26] and Cakmak,^[30] using laser ablation inductively coupled plasma mass spectrometry, have reported increase in Zn concentration in endosperm by Zn sprays.

Maize

Much information on Zn and Fe agronomic biofortification in maize through fertilizers is not available in the literature. Small holder farmers in South Africa, Zimbabwe, and other

African countries use very little amounts of chemical fertilizers and use of Zn fertilizers is negligible. A study in Zimbabwe showed that the application of cattle manure (supplying 113 g Zn ha⁻¹) + NPK and leaf litter (supplying 430 g Zn ha⁻¹) + NPK significantly increased Zn concentration in corn grain over NPK.^[31] Results from Indian Agricultural Research Institute, New Delhi, India, reported that for Zn biofortification of corn grain and stover, foliar application of 1 kg ZnSO₄ ha⁻¹ (in two sprays at tasseling and initiation of flowering) or application of Zn-coated urea is better than soil application of ZnSO₄. However, highest Zn concentration of 49.2 mg kg⁻¹ corn was recorded with 5 kg Zn to soil + 1 kg Zn as foliar, which was 22.4% higher than control (no Zn).^[32] The expected increase in Zn and Fe from plant breeding is likely to be lesser in corn than in rice and wheat.

Oats (*Avena sativa*)

In a study, Indian Agricultural Research Institute, New Delhi, India, reported that coating Zn as ZnO or ZnSO₄ onto oats seeds at 2 kg Zn per 100 kg seed (required for sowing 1 ha) gave a Zn concentration of about 32 mg kg⁻¹ as compared with about 25 mg kg⁻¹ obtained with soil application. For soil application, ZnSO₄ was better than ZnO.^[33]

Chickpea (*Cicer arietinum*)

Application of Zn to soil or foliage as ZnSHH or Zn-EDTA increased Zn concentration in grain and straw of chickpea.^[34] In the case of grain, three sprays of ZnSHH or, Zn-EDTA recorded significantly more Zn in grain than soil application or one or two sprays (Figs. 1 and 2). The two sources of Zn differed significantly, when two or three sprays were made; Zn-EDTA recorded significantly higher Zn concentration in grain than ZnSHH in both the years of study. With both the sources of Zn different methods of application were in the following order: three foliar

Fig. 1 Zn concentration [mg kg⁻¹ dry matter (DM)] in chickpea straw (mean of 2 years). Error bar indicates the critical difference (CD) value at 5% level of significance which is 2.66.

Fig. 2 Zn concentration (mg kg⁻¹ DM) in chickpea grain (mean of 2 years). Error bar indicates the CD value at 5% level of significance which is 3.32.

sprays > two foliar sprays > one foliar sprays or soil application; three foliar applications recorded the highest Zn concentration in straw. When soil applied or a single foliar application was made, Zn-EDTA recorded significantly more Zn in chickpea straw than ZnSHH straw.

CONCLUSION

Agronomic biofortification is the easiest and fastest way for biofortification of cereal grains or food crops with Fe, Zn, or other micro mineral nutrients in developing Asian and African countries, where cereals are the staple food. Agronomic biofortification is the only way to reach the poorest of the poor rural masses, who hardly have money to buy mineral supplements nor can afford to improve the components of their diet by incorporating more animal products. From the biofortification viewpoint, foliar application is better and requires lesser amount of Fe and Zn fertilizers than their soil application. Zn fertilization also increases grain Zn concentration in pulses, which are the major protein source in a vegetarian diet. This is important for developing countries especially like India, where a majority of people are vegetarian. When cultivars or genetically modified crops with grains denser in Fe and Zn are developed, adequate Fe and Zn fertilization will be necessary. The genetic and agronomic approaches are therefore complementary to each other and should progress in tandem.

Environment and Production Technology Division, International Food Policy Research Institute (IFPRI), Washington, District of Columbia, U.S.A.

Abstract

Agricultural soil water management is a critical variable in food production growth to meet food demand and improve food security. This entry reviews the influence of soil water management on crop production in both low-input and high-input agricultural environments. Technological and managerial options are available to significantly reduce soil water constraints and improve crop productivity growth and must be tailored to specific agroclimatic environments. The options must be supported with policy reforms to provide appropriate economic incentives for soil water management and, particularly in Africa, investment in infrastructure, communications, and markets.

INTRODUCTION

With growing incomes and world population being projected to reach eight billion in 2025, there remains great pressure on the agricultural sector to increase food production to ensure food availability and feed the growing populace. Effective soil water management to improve soil and water productivity is an essential element for food security. This entry reviews the evidence on the impact of soil degradation on crop productivity, assesses the constraints to productivity growth arising from ineffective soil water management, and proposes solutions to enhance productivity growth and food security.

IMPACT OF LAND DEGRADATION ON FOOD SECURITY

Soil degradation, in significant part, due to poor soil water management, has direct on-farm production costs (in the form of lower yields or greater production costs as more fertilizers and other inputs are applied to offset yield losses) and off-site costs (in the form of siltation of dams and irrigation systems and damage to mangrove swamps and coral reefs). Many studies have assessed the rates of land degradation for countries and regions, with a wide range of results. According to a widely cited global study, 14% of all agricultural land, permanent pasture, forests, and woodland suffered from serious soil degradation between 1945 and 1990.^[1] The study estimated degradation to be generally more prevalent in the developing countries: 31% of land in Central America, 19% in Africa, and 16% in Asia were considered to be seriously degraded. The share of degraded area was estimated to be highest on agricultural

land (38%), especially in the developing countries. The most common forms of soil degradation were soil erosion by water and wind, followed by soil nutrient depletion, salinization, compaction, and sealing and crusting. The economic costs of this land degradation are difficult to assess because it is hard to quantify the impact of land degradation on crop productivity due to complex soil fertility and crop yield relationships. However, based on the physical soil degradation assessed in that study, a global study estimated the 1945–1990 cumulative crop productivity loss from land degradation worldwide of 5–13% depending on the underlying assumptions.^[2] While another study estimated losses of 5–9%, considering cropland and pasture productivity.^[3] These cumulative losses are equivalent to a productivity drop of 0.10–0.20% per year. This decline represents a significant drag on cereal yield, which during the period 1970–2004 grew globally by 1.19% per year, and only 0.94% per year in the developing countries. Moreover, a review of the literature showed cumulative crop yield losses due to past erosion of 2–40% across all African countries, with a mean of 8.2% for the entire continent and 6.2% for sub-Saharan Africa (SSA).^[4] These national-level estimates confirm that land degradation can be devastating in some countries, especially in fragile environments.

SOIL WATER CONSTRAINTS ON AGRICULTURAL PRODUCTION IN LOW-INPUT AND INTENSIVE AGRICULTURE

In this section, we discuss soil water management constraints to agricultural production in two polar cases, the low-input system in Africa and intensive irrigated agriculture in Asia. Accounting for one-third of total GDP, 70%

full-time employment, and 40% total export earnings, in the early 2000s, agriculture is crucial to African economic development and food security. But population growth rates have exceeded the rate of production growth in many areas, leading to declining per capita food production. Crop yields in SSA are low (799 kg/ha in 1967) and have only grown slowly (980 kg/ha in 2005) compared with other regions. The green revolution that brought huge improvements to food security in Asia largely bypassed Africa, which is characterized by predominantly rainfed rather than irrigated agriculture, poor soil fertility and soil water management, less crop diversification, underinvestment in agricultural research and development and infrastructure, lack of competitive markets and conducive enabling environments, large and growing impact of human health on agriculture, low-labor productivity, minimal mechanization, limited access to agricultural inputs, credit, and poverty that limit farmer ability to buy inputs.^[5]

Inadequate soil water management practices in Africa have contributed to slow growth in production through soil fertility depletion, including limited adoption of organic and inorganic fertilizer replenishment strategies; inadequate adoption of soil and water conservation measures; declining use and length of fallow periods; expansion of agricultural production into marginal and fragile areas, such as cultivation on steep slopes or in arid areas without proper anti-erosion measures; use of animal dung and crop residues as fuel rather than as matter for soil enrichment; and the removal of vegetation through overgrazing, logging, development, and domestic use.^[6]

In intensive Asian cropping systems, soil water management is also an important factor in promoting—or undermining—food security. Growth in crop yields, especially rice and wheat, was very rapid in much of Asia from the introduction of modern high-yielding varieties in the mid-1960s through the late 1980s. But environmental and resource constraints adding to soil water management have also contributed significantly to the evident slowdown in yield growth. Increased land use intensity has led to higher input requirements to sustain yield gains. Particularly in irrigated rice systems, declining yield growth trends can be directly associated with the ecological consequences of intensive rice monoculture systems, plus buildup of salinity and waterlogging, use of poor-quality groundwater, nutrient depletion and mining, increased soil toxicities, and increased pest buildup, especially soil pests.

Inappropriate management of irrigation has contributed to environmental problems such as excessive water depletion, water quality reduction, waterlogging, and salinization. Poor irrigation practices accompanied by inadequate drainage have often damaged soils through oversaturation and salt buildup. However, intensification per se is not the root cause of lowland resource-based degradation. A policy environment that encourages monoculture systems and excessive or unbalanced input use is significantly to blame. Trade policies, output price policies, and input subsidies,

particularly for water and fertilizer, have driven excessive use of these inputs. The successful drive for food self-sufficiency in Asian countries with an exhausted land frontier came at a high ecological and environmental cost. Appropriate policy reforms at the macro and sector level will go a long way toward arresting degradation trends, but the degree of degradation in many regions will pose severe policy challenges.

SOLUTIONS

Solving food security challenges in the developing countries requires all the contributing factors to be addressed, but soil water management is a critical area where improvement in policy and management would improve food security.

Soil Quality, Fertilizer Use, and Nutrient Management

A number of approaches have been adopted to deal with soil infertility in SSA. These approaches consist of organic farming, high external input agriculture, low external input sustainable agriculture, and integrated soil fertility management. No single approach is likely to succeed because of the diverse agroclimatic contexts of the region.^[7] Integrated nutrient management (INM), which combines the application of chemical fertilizer and organic matter and use of other organic soil fertility practices such as agroforestry, relay cropping, soil erosion control, and tillage methods, will be essential.^[8,9] INM is often more sustainable than sole use of either chemical fertilizer or organic matter. Chemical fertilizer provides the macronutrients (nitrogen, phosphorus, and potassium) but does not provide the organic matter which is essential to soil fertility. On the other hand, organic matter such as manure is poor in phosphorus and potassium and contains only a small share of nitrogen.^[10]

A substantial increase in the use of inorganic fertilizer is therefore also essential to agricultural growth in Africa. Fertilizer use can be promoted through subsidies and vouchers, public investment in soil fertility enhancement technologies, locally tailored fertilizer recommendations, and coordinated service provision, including output markets and the use of public-private partnerships.^[11] The affordability of fertilizers is one of the major challenges in Africa. Subsidies can compensate farmers in remote areas for high-transport costs involved in supplying their inputs and purchasing their outputs. But many of the benefits of subsidies are captured by richer farmers who have the most effective demand for fertilizer. A more appropriate role for the government in enhancing fertilizer use would be to provide public goods, including agricultural market and transportation and communication infrastructure, and extension services, to advise farmers on the appropriate quantity, quality, and timing of fertilizer applications.

Sustainable and Efficient Water Use

Investment in small dams, groundwater development, and water harvesting offers a major opportunity for promoting agricultural production and improving livelihoods in some African regions. Simple and affordable innovations to tap shallow groundwater, such as treadle pump and small motor pump technology, have the potential to dramatically improve poor people's access to groundwater, as has been achieved in West African countries like Nigeria, Niger, and Chad. Shallow aquifers are also accessible using indigenous methods of well construction and low-cost techniques, such as hand dug wells and tube wells.^[12] However, aquifers should be utilized in ways that avoid undermining their sustainability. Investments and policies focused on innovative water management approaches for rainfed agriculture, like rainfall harvesting and moisture conservation-based farming, can also significantly improve Africa's future water resources scenario.

In Asia, overuse of water that has led to soil salinization needs to be addressed in a number of ways such as giving increasing priority to water efficiency investments within the irrigation system and on-farm production; watershed management, flood control, drought management, and drainage; the institutional and incentive framework for surface and groundwater management and conservation. The policy framework to establish incentives may be the most important. Water and power subsidies should be reduced or eliminated because they promote overuse and therefore distort user incentives toward conservation of water and cost-effective practices. The command-and-control approach is often the least cost-effective approach because of poor governance and complex property rights issues. A crucial policy reform would be the establishment of clear and secure water rights. Water rights empower users by requiring their consent to any reallocation of water and by receiving compensation for transferred water. Security of water rights tenure based on well-defined rights encourages investment in water-saving technology.

To further address the salinity and water-logging problems that have affected the irrigated and some rainfed areas in Asia, there is a need to improve development and dissemination of conservation tillage and water-harvesting technologies. This will also increase the water productivity and help to mitigate the effects of drought in the dry areas and increase the crop yield response to fertilizer and other inputs.^[9]

CONCLUSION

Inadequate soil water management constrains crop productivity growth and food security in both low-input African cropping systems and intensive Asian systems. Technological and management options are available to significantly reduce these constraints and must be tailored to specific agroclimatic environments. But these solutions will not be adopted without policy reforms to provide appropriate

economic incentives for soil water management and, particularly in Africa, investment in infrastructure, communications, and markets.

Food Security: Agricultural Productivity and Resources

Keith D. Wiebe

*Resource Economics Division, U.S. Department of Agriculture (USDA),
Washington, District of Columbia, U.S.A.*

Abstract

Soil resources and agricultural productivity affect food security both through their impact on food supply and through their impact on the incomes of that half of the world's people whose livelihoods depend directly on agriculture. Agricultural productivity depends in turn on a variety of factors, including the quality of soil and other natural resources. Resource quality has often received insufficient attention owing to the scarcity of appropriate data, but improvements in data and methods allow better understanding of the impact of differences in the quality of land, labor, institutions, and infrastructure on agricultural productivity, and thus on food security.

WHAT IS FOOD SECURITY?

Food security has been defined and used in many ways, but the World Bank's 1986 definition, "access by all people at all times to sufficient food for an active, healthy life," is typical of most.^[1] Access to food derives from opportunities to produce food directly or to exchange other commodities or services for food.^[2] These opportunities are based in turn on resources, including soil, as well as on production technologies, environmental and market conditions, and other factors.^[3]

To ensure food security, access to food must be sufficient under all possible circumstances in any particular period of time, because all sources of access are subject to variation. Food production varies with weather and other environmental factors, e.g., access to food via exchange depends on market factors such as wages and food prices. Access to sufficient food must also be sustainable over the long term. A household (or nation) can hardly be considered food secure in the long run if it is able to meet its nutritional requirements only by depleting its endowment of resources. Appropriate use and conservation of soils are thus central to the concept of food security.

TRENDS IN GLOBAL FOOD SECURITY

The world's population approached 6.4 billion in 2004 and continues to grow. Food production has grown even more rapidly in decades, increasing in per capita terms by 0.9% annually on a global scale, and even faster in China and other populous developing countries.^[4] Production growth notwithstanding, over 800 million people, most of them in developing countries, suffer from chronic food insecurity because they cannot produce or purchase enough food.^[5] The Economic Research Service projects that the gap

between what the poorest countries can produce or purchase and what they need to meet their nutritional requirements will grow by over 50% over the decade, owing in part to depletion and degradation of soil and water resources.^[6]

Population growth has slowed in years, but even so the world's population is projected to reach 7.5 billion by 2020. Almost all of this growth will occur in the developing world. Average incomes also continue to rise, and by 2005 over half of the world's population is expected to live in urban areas, with associated changes in dietary preferences.^[7] As a result of these factors, the International Food Policy Research Institute projects an increase of about 40% in world demand for grain over the period 1993–2020, primarily in the developing countries.^[8]

Such growth in food demand, representing an annual increase of 1.3%, is well within the range of growth in production since the mid-20th century.^[9] Yet historic rates of growth in both cultivated area and yields have slowed in years. The Food and Agriculture Organization (FAO) reports that only a third of the estimated 2.8 billion hectares of land with potential for crop production in the developing countries is in cultivation, but the costs of expanded cultivation are often high in economic and environmental terms.^[10] As a result of these costs, the FAO projects that area expansion will contribute only about 20% of production growth in 30 years. Increased multiple cropping and shorter fallow periods will contribute another 11%, while the majority of production increases (69%) is projected to come from increased yields. Global average cereal yield growth slowed from 3.0%/yr during the 1960s to 1.1%/yr during the 1990s,^[11] owing to reduced growth in input use, low cereal prices, and low levels of investment in agricultural research and technology. Poorly functioning markets and a lack of appropriate infrastructure and credit also contribute.^[8] Changes in soil quality may also play a role.

SOIL QUALITY AND AGRICULTURAL PRODUCTIVITY

Soils play a central role in food security, both in terms of food production and in terms of the livelihoods of farmers who produce crops other than food. Given limits on the expansion of agricultural land, increases in both food production and farmers' incomes depend critically on growth in agricultural output per unit of land, labor, and other inputs, i.e., agricultural productivity. While it has long been recognized that agricultural productivity depends directly on soil fertility, water-holding capacity, and other aspects of the quality of soil resources, these relationships have been difficult to quantify on global and regional scales owing to limitations of data and spatial variations in climate, topography, management practices, and other factors.^[12] Improvements in spatially referenced data and analytical methods have allowed better understanding of the relationship between soil quality and agricultural productivity.

To isolate and control the effects of differences between countries in land quality, Wiebe et al.^[13] used spatially referenced soil and climate data in combination with new high-resolution land-cover data to measure the share of each country's cropland that is not limited by major soil or climate constraints to agricultural production. Econometric analysis of this measure, controlling for levels of labor, fertilizer, and other inputs to agricultural production, indicates that in most regions of the world over the period 1961–1997, agricultural productivity was 20–30% higher in countries with above-average soils and climates than it was in countries with below-average soils and climates. Soil quality also influences the impact of other inputs on agricultural productivity. For example, fertilizer response in sub-Saharan Africa is significant and positive both in countries that have good soils and climate and in countries that do not, but the magnitude of the response is about twice as large in the latter countries.^[14] While these productivity impacts are estimated from differences in soil quality across countries, they suggest the importance of examining more closely the productivity impacts of changes in soil quality over time, i.e., soil degradation.

SOIL DEGRADATION AND FOOD SECURITY

Although data are limited, it is estimated that about 22% of the area under agriculture, permanent pasture, forest, or woodland worldwide has been degraded to some degree by physical, chemical, or biological processes since the mid-20th century.^[15] Numerous studies have documented the impacts of such processes on crop yields in specific locations, but extrapolation to larger scales is difficult. Rough estimates suggest that soil degradation has reduced global average agricultural productivity by about 0.1% annually.^[16] Such losses have historically been masked by increased use of inputs and improvements in production technology, and as

a result, it is generally agreed that they do not pose a threat to global food security. Degradation-induced losses may become more apparent, however, or more costly to mitigate, if yield growth continues to slow down.

Yield effects may also be much more severe in particular areas. In an analysis of over 300 original field studies around the world, Den Biggelaar et al.^[17] found that the impact of soil erosion on yields varied widely by crop, soil, and region. For example, wheat yields in Europe declined by an average of only 0.04%/yr as a result of soil erosion, while maize yields in Central and South America declined by an average of 0.94%/yr. Lal^[12] and Scherr^[18] report similar variation in impacts across crops, soils, and regions elsewhere in the world, with corresponding variation in the potential impact of soil degradation on food security.

Actual impacts in any particular location depend not only on crop and soil but also on climate, topography, and a host of other factors, including management practices. Understanding the impact of soil degradation on agricultural productivity and food security thus requires an understanding of the incentives farmers face when making choices about management practices.

INCENTIVES FOR SOIL USE AND CONSERVATION

Some forms of soil degradation—such as nutrient depletion—can generally be feasibly reversed given technologies and market conditions, but others—such as topsoil loss owing to erosion—are effectively irreversible. How soils are actually managed to avoid, minimize, or reverse degradation depends on a variety of factors influencing farmer decisions, including the prices of agricultural inputs and outputs, farmer characteristics, and land tenure.^[19] Where markets function well and property rights are well defined, farmers generally have an incentive to manage soils to protect their long-term productive potential.^[20] Where land tenure is uncertain or access to credit is limited, on the other hand, this incentive may be weak and farmers may not find it optimal to adopt costly soil conservation measures.^[21]

In addition to its effects on productivity, soil degradation may also affect water quality, siltation in reservoirs, flood frequency, and other outcomes.^[22] As these impacts are felt off-site, farmers generally need additional incentives to address such concerns sufficiently. These concerns motivate policy measures to encourage increased adoption of conservation measures by farmers in many countries, including farmers in the United States.

CONCLUSION

Growth in global population, incomes, and food demand presents continuing challenges for agriculture in the 21st century. New technologies offer considerable potential

to maintain and improve soil quality, agricultural productivity, and food security, and evidence suggests that soil degradation has had a relatively small impact on global agricultural productivity. Actual resource management strategies and outcomes vary widely with circumstances, however, and depend critically on the incentives and institutions faced by farmers. The greater the spatial scale of potential costs and benefits, and the farther they are into the future, the greater is the challenge for policymakers to structure appropriate incentives and institutions, and the greater is the importance of research and improved understanding of the alternatives available.

Food Security: Soil Degradation, Global Scale

Michael A. Zoebisch

German Agency for International Cooperation, Tashkent, Uzbekistan

Eddy De Pauw

International Center for Agricultural Research in the Dry Areas (ICARDA), Aleppo, Syria

Abstract

Growing populations lead to an increasing demand for food. With decreasing per-capita areas of arable land, this leads to additional pressure and stresses on the limited land resources, especially the soils. As a consequence, large parts of the world are affected by soil degradation, and this has a direct effect on food security.

INTRODUCTION

Food security is commonly defined as the access by all people at all times to enough food for an active, healthy life. Extended concepts include food quality aspects, cultural acceptability of the food, equitable distribution among the different social groups, and gender balance.^[1–4] These concepts imply that, in addition to producing enough food, people must also have access to it. This opens the arena for the socioeconomic, cultural, policy, and political dimensions of food production and supply. Thus, food security—and consequently food insecurity—are multidimensional. It is not possible to separate clearly the biophysical and socioeconomic dimensions of food security, because they are closely interrelated and interdependent.^[2] However, the most limiting natural resources needed for food production are soil and water. If these resources are depleting, land productivity—the key factor for crop production—declines, and the land is no longer capable of producing the biomass needed for direct and indirect human consumption. If soil degrades, its plant-life-supporting functions are lost, together with its role in the hydrological cycle. Soil is a limited resource and, because of the long duration of soil-forming processes, can be considered as non-renewable. The production of food and feed is directly linked to the productive capacity of the soil. The degree and extent of soil degradation and, consequently, its effect on food production are dependent on how the land is used.

UNDERNOURISHMENT—A MAJOR INDICATOR OF FOOD INSECURITY

The proportion of chronically undernourished people is a manifestation of the degree of food insecurity. Worldwide, more than 830 million people are undernourished; 800 million of these people live in the developing countries,

i.e., about 18% of the population of these countries.^[1] Table 1 shows that the most seriously affected region is sub-Saharan Africa, with 33% of the population chronically undernourished. In Asia and the Pacific, chronic undernourishment has decreased significantly over the past decades.

Yields of the major food crops in many countries of these regions have risen remarkably. But in most cases the yield increases have not been able to keep pace with the needs of growing populations. Subregional trends, especially from Africa, China, South Asia, and Central America, indicate large yield declines due to soil degradation.^[2,6,7] Countries of the less degraded temperate regions can substitute for the losses in other regions. However, in the affected areas, food prices will increase and hence the incidence of malnutrition. Densely populated countries and regions that depend solely on agriculture will be most affected. As input requirements—and their costs—grow with increasing degradation, these countries will probably not be able to maintain adequate levels of soil productivity without special efforts to stabilize the system.

VULNERABLE AREAS

Only about one-tenth of the world's arable areas are not endangered by degradation. Most soils are vulnerable to degradation and have low resilience to fully recover from stresses. The soils in the tropics and subtropics are more vulnerable to degradation than those in temperate areas, mainly due to the climatic conditions.^[8] The total land area available for agricultural production is limited. Different types of land have different capabilities and limitations. Not all land is suitable for cultivation. The major natural limiting factors for soil productivity are steep slopes, shallow soils, low levels of natural fertility, poor soil drainage, sandy or stony soil, salinity, and sodicity.

Different agroecosystems are typically susceptible to different types of soil degradation.^[7–9] In mountainous

Source: From Lal & Singh.^[5]

areas and steep lands, water erosion is the dominant form of soil degradation. For arid areas, both water and wind erosion and the loss of soil organic matter are typical. In humid areas, soil acidification and fertility decline are of importance. In irrigated areas, the hazards of soil salinization and waterlogging are of special significance. Knowledge of these hazards can help understand the limitations of the land and introduce appropriate land use practices that reduce soil degradation and loss of soil productivity.

UNDERLYING CAUSES

Misuse of Land

The main causative factors of human-induced soil degradation, in a broad sense, are overuse and inappropriate management of agricultural land, deforestation and the removal of natural vegetation, and overgrazing as well as industrial activities that pollute the soil.^[7] Worldwide, soil erosion by wind and water is the most important form of

soil degradation, accounting for between 70% and 90% of the total area affected by soil degradation.^[6,7] High population pressure and the resultant increased need for higher land productivity are the main factors leading to inappropriate and exploitative land use.

In high-input systems, loss of soil quality due to degradation can be compensated to a certain extent by inputs, such as fertilizers and irrigation water. In low-input systems—usually practiced by resource-poor farmers (in poor countries)—soil quality contributes relatively more to agricultural productivity.^[10] Therefore, soil degradation in these systems has more drastic and immediate effects on soil productivity and, hence, food production.

Pressure on the Land

When the land is not enough, i.e., when land scarcity becomes a limiting factor for food production, people usually resort to intensification of their land use and opening up new, often unsuitable, land for cultivation.^[4,10] Both pathways will most certainly lead to soil degradation, if unsuitable land use technologies are used. The majority of land users in the developing world do not have adequate access to appropriate land use technologies and the financial means to invest in their land.^[1] The area available for crop production therefore puts a definite limit to sustainable food production in many parts of the developing world. Alternative, i.e., non-agricultural means of income generation would enable the people to supplement their food requirements on the market and could relieve immediate pressure on the land. This would save soil and land resources.

Losses and Gains of Agricultural Land

Estimates show that more than 10 million hectares of agricultural land worldwide is lost per year, most of it due to soil degradation and also due to urbanization (i.e., between 2 and 4 million hectares).^[4] Annual deforestation and clearing of savanna land accounts for about 20 million hectares, of which 16 million hectares is converted to cropland. Thus, there is an annual net gain of cropland of about 5–6 million hectares. Most of these converted lands can be considered marginal, i.e., less suitable for cropping. Loss of traditional sources of grazing and firewood, together with the ecological functions of forests, i.e., their role in regulating watershed hydrology, is the factor inducing the degradation of soil.

MINIMUM PER-CAPITA CROPLAND REQUIREMENT

On a global scale, it is estimated that the minimum per-capita area of cropland required to produce an adequate quantity of food is around 0.1 ha.^[2,6] This rough estimate is dependent on many different location-specific factors and circumstances, such as soil, terrain, climate, farming

system, and land use technology. However, it permits a suitable comparison at the overall global scale. Estimates predict that a large number of countries will have reached the 0.1 ha limit of per-capita cropland by the year 2025.^[1,2,8] In the absence of more land for cultivation, future food needs of the people in these countries will have to depend on increased soil productivity through intensified land use. Resource-poor farmers with no option to expand their cultivated area usually cannot invest in necessary soil conservation and soil fertility maintenance measures. Over time, this leads to nutrient depletion and other forms of soil degradation that affect soil productivity.^[4,5,10]

Although some developing countries have indeed increased their yields on a per-unit area basis significantly, these increases cannot compensate for the increased demands by growing populations. Table 2 illustrates past and future trends in per-capita available cropland in selected countries with high population growth and gives examples of yield level trends. The table shows that, to a large extent, the gains in yields are offset by the decrease in available cropland to grow the required total quantities of crops to feed the population. In these countries, food insecurity can directly be related to the pressure on the land or land scarcity.

The growing pressure on the land is a reflection of not only population growth and the direct needs for food, but also changed diets and increasing financial needs (by the

land users) that have to be met from land cultivation, putting additional stress on the soil resources.

ESTIMATING SOIL DEGRADATION ON A GLOBAL SCALE

Limitations of Methodology

The scientific relationships between different soil degradation processes and soil productivity have been established mainly on field and plot level.^[5,12] Although reliable data are available for a wide range of different agroecologies and farming systems, they cannot give a precise picture of degradation-dependent soil productivity for larger land units. The increasing complexity of the determining factors and processes on larger land units, the endless array of location-specific conditions, and the lack of adequate data make upscaling extremely difficult for country and regional levels. Estimates of the extent and severity of soil degradation—and their effects on soil productivity—on a country, regional, continental, and global levels therefore bear a substantial degree of uncertainty. Most estimates use the methodology developed by the Global Assessment of Human-Induced Soil Degradation (GLASOD) project.^[6,7] The GLASOD estimates are based on expert assessment and are therefore largely subjective. However, the

Table 2 Trends of available per-capita cropland and average yield levels of main staple crops for selected countries.

methodology has been widely adopted, and GLASOD estimates of soil degradation are accepted as the best estimates available. Global estimates are, therefore, only rough approximations and should not be taken literally.

Effects on Soil Productivity and Food Production

Table 3 shows estimates of degradation and cumulative losses in soil productivity on a continental level for different land use types. The figures show that, overall, Africa and Central America are the most severely affected continents, in terms of both soil degradation and reduction of productivity; 65% of African and 75% of Central American cropland are affected by soil degradation. The overall loss in productivity in these two regions over the last years is estimated between 25% and 37%. On a continental basis, Africa has land reserves, but large areas of the continent are marginal for crop production, and their food production is therefore most seriously affected by degradation. Europe also shows relatively high trends in degradation, but mainly of pastures and forests. Productivity losses generally are low, as for North America and Oceania (i.e., mainly Australia), and these can most probably be compensated for by improvements in technology and input supply.

A more detailed picture of trends in food productivity for the main food cereals in selected countries with high population growth rates and agriculture-based economies is given in Fig. 1. The overall past trends in the different countries show a consolidation of per-capita food production. However, the projections until 2025 indicate clear decreases. This suggests that long-term food security in these countries is at stake.

SOIL DEGRADATION AND DECLINE IN PRODUCTIVITY

Over the past decades, the cumulative loss of productivity of cropland has been estimated at about 13%. However,

aggregate global food security does not appear to be under a significant threat.^[2,6] There is no conclusive evidence that soil degradation has in the past affected global food security. We cannot conclude to such relationship because

Fig. 1 Per-capita production of selected crops in countries with high population pressure.

Source: From Engelman & LeRoy^[2] and FAO.^[11]

1) the database on the extent and magnitude of various types of soil degradation is inadequate; and 2) the impact of soil degradation on land productivity is very site specific, often anecdotal and difficult to quantify at regional and global levels. In fact, globally, per-capita food production has increased by about 25% since 1961 when the first production surveys were conducted by Food and Agriculture Organization of the United Nations (UN).^[1,11] The yields per unit area of the major cereals (i.e., wheat, rice, and maize) have steadily increased and are rising.^[1,11] This, however, does not imply that sufficient food is—and will be—available in all countries and regions. Food is not necessarily produced where it is most needed. A top priority should therefore be to improve inventories of land degradation at regional, national, and subnational levels.

However, the evidence is conclusive that soil degradation affects food security at the subnational and national levels in the developing countries by the gradual decline of the land's productive capacity and that this trend will continue in the future. We therefore have to assume that, eventually, land degradation will constitute a serious threat to global food security by its particular impact on the developing countries. According to most scenarios, these countries are most vulnerable to degradation induced by increasing pressure on their land resources, the effects of climate change, and their inability to finance programs to rehabilitate affected areas and prevent further degradation and decline of productivity.

Food Security: Soil Degradation, Local and Eco-Regional Scale

Sara J. Scherr

Forest Trends, Washington, District of Columbia, U.S.A.

Abstract

Soil degradation is widespread, and its pace has certainly accelerated in developing countries. Current and future soil degradation hot spots include areas with degradation-prone soils, inadequately managed irrigation, and rapidly intensifying production without the technology or the economic incentives for good resource husbandry. Thus, while posing particular problems for the poor, soil degradation is likely to have far-reaching impacts on economic development in many agriculture-dependent countries.

INTRODUCTION

An estimated 16% of all agricultural land in developing countries, and a much higher proportion of cropland, has experienced significant soil degradation since the middle of the 20th century. Deterioration in the physical or chemical attributes of these soils has reduced agricultural yields and increased production costs. Large land areas—an estimated 5–7 million hectares (ha) per year—have gone out of production entirely.^[1,2] Degradation appears to have had little impact on food availability or prices in international markets because of the global capacity for substitution and the dominance of temperate producers.^[2] However, international trade plays a minor role in food supplies in most poor countries, and especially in most poor rural areas, largely because of a lack of income to purchase imported food and, in some cases, poor transport and market infrastructure. Thus, many areas undergoing serious soil degradation are experiencing reduced food supply and farm income, in some cases on a scale large enough to slow economic development. Degradation especially threatens the livelihoods of poor producers, who have limited access to capital inputs and for whom the underlying quality of agricultural soil is the principal determinant of farm productivity.

The period since World War II has seen remarkable growth in rural population, agricultural land area, and agricultural productivity in the developing world. Although the annual rural population growth rate declined from 2.2% between 1960 and 1965 to 1% between 1990 and 1995, the absolute number of rural dwellers grew by almost 40%, from 2.0 to 2.8 billion. Total growth rates of agricultural production in developing countries have rivaled or surpassed historical growth rates in industrialized countries, though not on a per capita basis. This growth came in part from extensive land clearing but

primarily through yield increases. It is not surprising that rural population increase, area expansion, and widescale intensification were associated with widespread soil resource degradation.^[2]

NATURE OF SOIL DEGRADATION

The nature of soil degradation has varied according to the particular pathways of agricultural intensification, reflecting different pressures and resource endowments. *Irrigated lands* have expanded and become highly productive as beneficiaries of Green Revolution technologies. However, poor water management has led to widespread salinization and waterlogging, while subtle nutrient management problems associated with multiple cropping have slowed yield increases. In *high-quality rainfed lands*, with naturally fertile, less weathered soils and lower climatic risks, cropping intensity also increased greatly. But inappropriate machinery use has sometimes led to soil compaction, and poor vegetation management has exposed soils to erosion. Substitution of organic inputs with chemical fertilizers has led to declining organic matter, acidification of vulnerable soils, and changes in soil fauna. In *densely populated, marginal areas*, low-quality and degradation-prone soils, which were traditionally managed through moderate- to long-fallow systems, are under continuous cultivation. Erosion from poor soil cover and nutrient depletion from inadequate management of organic matter and fertilizers are common results. In *extensively managed, marginal lands*, degradation has been caused principally by the land-clearing process itself, by nutrient depletion due to declining fallow periods, by widespread burning to control weeds and pests and provide ash for plant nutrition, and in rangelands by overgrazing. The importance of *urban agriculture* accelerated dramatically in

the 1980s, contributing to food security, income generation, and recycling of urban wastes but also to some environmental problems. Soil contamination with urban pollutants may pose a health hazard to consumers and reduce production, while insecure land access and tenure discourage sustainable grazing and soil management practices.

The concerns of policymakers regarding agricultural soil degradation relate not to its extent or severity but to its demonstrated impact on the following policy objectives:

- aggregate supply, stability, or price of agricultural output (i.e., if lands with degrading soils are a significant source of market supply for national consumers or export markets and alternative sources of supply not available or economic);
- agricultural income or economic growth (i.e., if soil degradation reduces agricultural income and its economic multiplier effects, through lower production or higher costs, and alternative sources of economic growth are limited or expensive to develop);
- consumption by poor farm households (i.e., if lands with degrading soils are a critical source of food security for subsistence or semisubsistence producers with few alternative livelihood options); or
- national wealth (i.e., if degradation reduces the long-term productive capacity of soil resources deemed to be of future economic or environmental significance, threatening the resource base and food security of future generations).^[2]

Environmental effects of soil degradation—including off-site damages from sedimentation and diminished watershed function as well as habitat alteration and reduced carbon sequestration—are also of interest to policymakers.

Considerable evidence of the economic and food security impacts of soil degradation has been produced since the late 1980s, although results must be interpreted cautiously.^[2] Weaknesses include uneven geographic coverage and numerous methodological and data problems.^[3] For many soil types, there is little information about the productivity impacts of degradation, the costs of rehabilitation, and the thresholds for soil quality below which investment in restoration will be uneconomic.^[4] Most studies use simplistic models of degradation–yield–income relationships, ignoring the dynamics of markets and farmer response that have been widely observed in field studies.^[5,6] Only a few studies explicitly document the impacts of soil degradation on consumption by the rural poor. Still, the weight of the evidence (summarized in the following section) suggests that the magnitude of agricultural supply and economic growth impacts of soil degradation justify more active policy engagement.

AGRICULTURAL SUPPLY

Asia

In Asia during the 1980s, it was estimated that over one-third of irrigated areas and over one-half of dry rainfed areas had experienced at least a 10% loss in productive potential, and 8% of irrigated and 10% of rainfed dry areas had suffered more than a 25% loss. Soil productivity losses of at least 20% from human-induced water erosion was well confirmed in eight countries, and presumptive evidence of such losses was documented in five other countries. Wind erosion was found to have little effect.^[7]

The 1995 expert survey found that soil degradation had moderate or worse impacts on agricultural productivity on one-tenth of all lands in South and Southeast Asia, with serious fertility decline or salinization affecting 15% of arable land.^[8]

Field-based evidence confirms supply effects. A synthesis of survey and experimental data in India concluded that 48% of soils had suffered a productivity loss of over 33%.^[9] Salinization and waterlogging in four villages of Uttar Pradesh, India, reduced paddy yield by 61% and wheat yield by 68% over 10 years.^[10]

In Bangladesh, deteriorating nutrient balance and organic matter decline led to an annual 0.36-ton decrease in total factor productivity in an intensive cropping system.^[11] In irrigated districts of the Pakistani Punjab, soil degradation lowered aggregate economic growth from 1966 to 1997 in four farm production systems by 0.58% per year; in the wheat–rice (*Triticum sativum*–*Oryza sativa*) system, resource degradation more than cancelled the effects of technological change.^[12] In China, grain yields would have been 30% higher between 1983 and 1989 in the absence of erosion, salinity, and degradation due to increased cropping intensity.^[13]

Africa

Soil experts estimated that in the 1980s over one-half of dry rainfed areas in Africa had experienced at least a 10% loss in productive potential, with irreversible productivity losses of at least 20% due to erosion in large parts of 11 countries.^[14] Cropland productivity loss from all types of soil degradation between the mid-20th century and 1990 was estimated to be 25%.^[15] In 1989, crop yield losses resulting from past erosion were calculated to range from 2% to 40%, with a mean of 6.2% for sub-Saharan Africa.^[16]

Evidence from field studies and cropping system models is variable. A Malawi study found crop-specific soil erosion impacts ranging from 4% to 11% per year yield losses.^[16] Models of maize production in four highland farming systems predicted significant yield declines, even with fertilizer use, although cotton

(*Gossypium* spp.) and coffee (*Coffea* spp.) yields were more stable. Fertilizer-induced soil acidification reduced highland maize yield to zero in 20 years; even with lime, yields were projected to drop by half in 30 years.^[17] National- and district-level regressions for maize (*Zea mays*) and sorghum (*Sorghum vulgare*) yields in Lesotho and for maize yields in Zimbabwe found no statistically significant relationship with erosion, possibly due to the dominant effect of climatic variation.^[18,19]

Central America

The cumulative loss of agricultural productivity due to soil degradation was estimated by soil experts to be especially high—nearly 37%—in Central American croplands.^[15] Most cost-benefit models in the region predict large yield that declines without soil conservation measures.^[20] Bioeconomic-model simulations predicted that between 1991 and 2000, soil erosion in Nicaragua would result in 16–21% reductions in output for sesame (*Sesamum indicum*), beans (*Phaseolus* spp.), maize, cattle, and cotton; large declines in coffee, cotton, and sesame exports; and price increases of over 25% for maize, beans, and cattle.^[21] Because they find ways to manage their soils, farmers generally report lower estimates of production impact when surveyed. For example, a national sample of smallholders in hilly El Salvador reported erosion-related productivity problems in less than one-fifth of sloping farm fields.^[22]

ECONOMIC GROWTH

Asia

The annual cost of soil degradation in South Asia in the early 1990s was estimated to be \$9.8–\$11.0 billion, the equivalent of 7% of aggregate agricultural gross domestic product (AGDP). Water and wind erosion accounted for over two-thirds of the loss, salinization and waterlogging for one-fifth, and soil fertility decline the rest.^[23] Other studies of China, India, Java, and Pakistan calculated impacts ranging from less than 1% to 5% of AGDP.^[2] In Java, one-year costs of erosion in 1984 equaled 4% of the annual value of rainfed farm output—the same order of magnitude as annual recorded growth in uplands production.^[24] In the irrigated wheat-rice system of the Pakistani Punjab, degradation also entirely offset productivity gains from other sources.^[12] The economic loss from degradation in China in the late 1980s was equal to China's entire budget for rural infrastructure investment, though less than 1% of AGDP.^[25] An econometric analysis of soil erosion and salinization using district-level data in China showed more serious impacts in poorer and more densely populated areas.^[26] Yet despite nutrient

depletion, the economic value of topsoil rose by nearly 8% between the 1950s and 1980s as a result of shifts to soil-preserving products, yield increases, and actions to reduce soil alkalinity.^[27]

Africa

Bojö^[28] evaluated evidence on the economic losses due to soil erosion from 12 studies completed in eight countries in sub-Saharan Africa. He found low gross annual immediate losses for hill agriculture in Madagascar, the Ethiopian highlands, Mali, and South Africa. Losses were significantly greater in Ghana, in another Ethiopian study, and in Zimbabwe for nutrient replacement alone. The gross discounted future loss from degradation varied from under 1% to 18%, and the gross discounted cumulative loss (which assumed a continued process of degradation over time) for five countries ranged from under 1% to 44%, of AGDP. Further estimates,^[29] based on replacement cost of depleted nutrients (calculated from nutrient balances predicted for 2000), are much higher than others based on productivity loss. Farm monitoring in Kenya found that the average cost of replacing depleted soil nutrients equaled 32% of average net farm income.^[30] A model was developed for Ghana to calculate the impacts of soil erosion, acidification, and nutrient depletion on different crops and agroecozones and trace their effects through the national economy. Comparing the baseline scenario over 8 years, with and without soil degradation, showed agricultural productivity losses of 2.9% per year. Even with greater fertilizer use, such losses would lower economic growth by one percentage point. In some scenarios, real GDP is reduced as much as 4.8% in the eighth year.^[31]

Central America

The few estimates of agricultural income effects in Central America are high. The annual cost of replacing nutrients lost through soil erosion in Costa Rica was estimated at 5.3–13.3% of annual value-added in agriculture that year.^[32] The average cost of soil erosion in areas planted to maize in Mexico represented 2.7% of AGDP, reaching 12.3% in the areas with highest erosion effects. Economic losses were nine times higher in the highlands and semi-arid regions than in the lowland tropics and four times higher without than with soil conservation.^[33] A model for Nicaragua projected that annual productivity loss due to erosion in 1991 would reduce GDP, imports, exports, and consumption in 2000 by 4–7% from the baseline scenario without erosion and investment by 9%. Erosion would raise the producer and domestic price indexes by 1.7% and 2.1%, respectively, compared with the baseline, while consumer price indexes would rise 4.0–5.8% for different social groups.^[2]

CONCLUSION

Soil degradation is widespread, and its pace has certainly accelerated in developing countries. Major productivity declines have resulted in some parts of Africa, Latin America, and Asia. The principal impacts appear to be on food consumption by the rural poor and agricultural income in areas where alternative livelihood options, sources of food supply, or non-agricultural development potential have been limited. Current and future soil degradation “hot spots” include areas with degradation-prone soils (particularly in sub-Saharan Africa), inadequately managed irrigation (particularly in South Asia), and rapidly intensifying production without the technology (many densely populated marginal lands) or the economic incentives (extensively managed marginal lands) for good resource husbandry.^[34] Thus, while posing particular problems for the poor, soil degradation is likely to have far-reaching impacts on economic development in many agriculture-dependent countries.

Thomas Fox

Forest Resources and Environmental Conservation, Virginia Polytechnic Institute and State University, Blacksburg, Virginia, U.S.A.

Abstract

Forest Soils is the science of dealing with soils as a natural resource supporting forest ecosystems. It is a soil that has developed under, and is currently supporting, a forest cover, yet these soils may have a past history having once been cropland or pasture and then converted back to forest. Management of these soils and the forests they support encompass a range of intensities – from very intensive to a hands-off approach. The most significant aspect of the modal forest soil is its closed nutrient cycle with the forest. This is what often separates the concept of a forest soil from cropland soils. Other unique aspects of Forest Soils are the long time frame between harvests, the low erosion rates, the low rates of fertilization under intensive management, the presence of a forest floor and the potential to use very deep soil horizons for sustenance. The history of research of Forest Soils covers soil/site relationships, nutrient cycling, long-term productivity decline, soil fertility management, and off-site effects of management, among others. As management intensity increases and rotation age decreases the differences between forest soils and cropland soils converge.

INTRODUCTION

Forest soil science is a well-established field of study, having developed as a specific subdiscipline of soil science in Europe in the late 1800s. This is illustrated by both the number of textbooks and the dates of the texts published in this area (Table 1). Other soil scientists have asked: “If there is a subdiscipline called forest soils, why not also study corn or tomato soils?” The justification for forest soil science is twofold. First, a long-lived forest cover imposes a unique set of characteristics on the soil in which it grows. Second, and probably of equal importance, is that the soil characteristics and processes important to the forest soil scientist are often not of great concern to cropland soil scientists for whom the biological and economic time frames of food production are relatively short (Table 2). In order to understand “Why study forest soils?” it is useful to first define the science and then discuss the soil/ecosystem characteristics that are unique to forest soil. The Soil Science Society of America defines soil science as “the science dealing with soils as a natural resource on the surface of the earth including soil formation, classification and mapping, physical, chemical, biological, and fertility properties of soils per se; and these properties in relation to the use and management of soils.”^[1]

In this context, the following definition is offered. Forest soil science is “the science dealing with soils as a natural resource on the earth’s surface which supports a forest

ecosystem. It includes how the forest influences, and is influenced by, soil formation and soil physical, chemical, and biological properties. It addresses how soil properties affect the sustainable use of the soil for the production of multipurpose forest outputs including, but not limited to, wood products, wildlife, water, and the maintenance of ecosystem services.”

WHY FOREST SOILS?

A forest soil is one that developed under, and is currently supporting, a forest cover. Forest soils include soils that have developed under continuous forest cover, soils that are supporting a forest cover different from the native vegetation, and soils that were once in cropland or pasture and have been converted back to a forest. Therefore, the chemical and physical properties of a forest soil are determined by the conditions under which it was formed as well as its more recent land use history. At one time, forests covered approximately 50% of the terrestrial surface of the earth. That has been reduced to around 30% as forests were cleared for other land uses such as pasture and row crop agriculture. The remaining forests are often located on steep slopes or on soils that are rocky, infertile, and with excessive or limited moisture. Forests can be remote from markets and urban areas limiting development pressure, which, combined with land ownership patterns and environmental policy, are reasons why agriculture has not

claimed these soils. Forest soils can be highly variable but what they all have in common is that they support a forest ecosystem, managed or unmanaged.

Historically, forest soil management encompassed a range of intensities depending on the product to be

produced and the economic value of that product^[2] (Fig. 1). The intensity of management represents a significant difference in perspective between forest soil scientists and cropland soil scientists. In the most intensively managed forests, the time required to grow a forest to a useful size is about 7 years. In the least, the forest is preserved in perpetuity with no intent to harvest wood products. The relatively long management time frame means that soil processes and properties, which have minimal importance in cropland systems, can be controlling factors in forest soils (Table 2).

A closed nutrient cycle is one of the most significant processes that separates a forest soil from an agricultural soil. The time between management interventions, if any, allows organic soil horizons (forest floor) to form above the mineral soil surface. The degree of organic matter incorporation into the surface mineral soil will produce a range of

Table 2 Contrast of soil properties, processes, and management strategies between forest soils and cropland soils (management contrasts are for intensive forest management vs. intensive cropland management).

Property/process/ management	Forest soil	Cropland soil
Time between harvests	Seven years to indefinite	Annual to biannual
Nutrient cycling	Closed	Open
Erosion	Very low	High
Topography	Level to very steep	Level to moderate
Fertilization practices	Low amounts applied one to several times per rotation	Annual high amounts
Irrigation	Not employed	Employed
Soil temperature	Buffered by a forest canopy	More variable
Utilized soil depth	Deeper	Shallower
Stoniness	None to high	Low
Remoteness from markets	Close to remote	Close
Surface soil organic horizons	Present	Absent

forest floor types. These organic horizons are unique to forest soils and strongly influence carbon and nutrient cycling in forest ecosystems. Cycling of some nutrients such as potassium is rapid while other nutrients such as nitrogen and phosphorus may be immobilized and only slowly released through time.

Due to the perennial nature of forest cover, and the infrequent management interventions during stand development, roots are capable of growing, surviving, and functioning at depth, allowing the forest stand to define a greater soil depth and to exploit water resources that short-lived agricultural crops might not find. The concept of the solum that includes the A, E, and B horizons and is thought of as the zone of pedogenic processes driven by biological activity does not always apply in forest soils where tree roots can extend throughout the C horizon and into the R horizons. Where cropland is most commonly defined by monocultures and where fertilization controls soil fertility, forest soils generally support a diverse plant community where groups of species may have their own strategy for using the soil's resources.

Wood products generally have low economic value compared to agricultural crops. Therefore, low-intensity management can be required in order to gain an economic return on the investment. In some circumstances, wood products are not the primary goal of management. That goal might be water yield and quality, wildlife, or maintenance of biodiversity. The latter objectives require an advanced understanding of how the entire forest ecosystem functions as well as of the multitude of consequences (on-site and off-site) that might come from human intervention. In this sense, Ecological Economics and the valuation of ecosystem services have been a part of forest management concepts for generations.

Consequently, forest soil scientists are often more interested with the O horizon, deep rooting, nutrient cycling, a tree's ability to thrive under native soil fertility, soil properties that influence the long-term productive potential of a forest stand that experiences periodic disturbances such as forest harvesting, climatic shifts, and anthropogenic inputs. Many of these are of little concern to cropland soil scientists.

In some intensively managed forests, such as eucalyptus in South America, forestry takes an agronomic approach where soil properties and processes are actively manipulated to optimize productivity. As forest management becomes more intensive, forest soil management moves toward the timescale of other cropland ventures, and the differences between forest soil science and other areas of soil science become less clear.

CONTRIBUTIONS OF FOREST SOILS TO SOIL SCIENCE

Like many scientific fields, the discipline of forest soils has evolved through time in order to better meet changing societal needs. Yet the accomplishments in forest soil science

during the 1900s testify to its importance in ecology, forest management, and forest conservation. The following is not meant to be a compilation of research in the area but is offered to show this field's breadth and depth.

FOREST ECOSYSTEM NUTRIENT CYCLING AND LONG-TERM PRODUCTIVITY DECLINE

Evaluating and developing forest management strategies based on nutrient cycling have been a collaborative effort of ecologists, silviculturalists, tree physiologists, and forest soil scientists. Nutrient cycling is often the basis for both sustainable soil management and forest harvesting schemes. A problem that constantly haunts forest managers is whether their harvesting regimes allow for sustainable forest productivity.^[3] Defining the soil's role in nutrient cycling as related to mineralization, exchange reactions, water regime, and root depth has been crucial in defining a site's ability to maintain sustainable forest growth.

SOIL DEVELOPMENT AND SOIL-SITE RELATIONSHIPS

One of the five soil-forming factors is the influence of vegetation. The influence of different species on soil formation is well known, as is the influence of the soil on forest ecosystems. This is best seen in the surface 20–40 cm of mineral soil. The study of forest soils has defined soil changes that occur under different types of forest vegetation. The research to describe and classify the different types of forest floor (mor vs. mull)^[4] is indicative of this type of influence. The ability of low-nutrient-demanding conifers to ameliorate a degraded soil and make it more productive for nutrient-demanding hardwood species has been well established.^[5] Podzolization has been linked with certain types of conifers that provide the acidic litter and soluble organic compounds that are responsible for sesquioxide movement in soils as well as soil acidification.

As forest ecosystems are related to the soils on which they grow, species have been matched to sites that meet their autecological requirements. Likewise, the productivity of a species will change with changes in soil characteristics. Soil-site studies have demonstrated broad general relationships between soil properties and forest ecosystem properties. However, we have to resolve the underlying causal relationships, most likely due to the highly empirical nature of the studies.^[6] Such work provides an appreciation of the range of site characteristics of economically important forest species and provides clues as to why their growth patterns vary on different soils.

FERTILITY OF FOREST SOILS

Soil fertility is probably the most studied topic in forest soil science. Evaluation of nutrient deficiencies and testing of

fertilization practices to correct deficiencies have provided productive forest management strategies throughout the world. Given the fact that many soils are not in cropland because of their inherent low fertility, commercially productive forests require nutrient management strategies that will allow large growth responses to minimal fertilizer inputs.

OFF-SITE EFFECTS OF FOREST MANAGEMENT

Probably, the most controversial environmental debates of the late 1900s in which forest soils played a role concerned the off-site effects of forest harvesting on water quality. Studies at the Hubbard Brook Experimental Forest forced scientists to evaluate whether harvesting could be responsible for serious nutrient losses and detrimental off-site effects. These articles set off a flurry of soil research on mineralization rates, water flow in forest soils, leaching losses through forest soils, and soil recovery from degradation. The stimulation was healthy in that it produced a compendium of information, from a wide range of landscapes, showing how soil treatments influence water quality.

The influence of acid deposition, both in the United States and in Europe, stimulated another round of research on forest soils. Soil's natural buffering against acidification, leaching of aluminum from soils, nitrate loading of soils by pollution, and amelioration practices to combat the effect of acid deposition were all topics of interest that stimulated research and provided a better understanding of the soil resource.

CONCLUSION

In conclusion, forest soil science is a crucial discipline in the management of our natural forest resources. Tall trees use the soil for physical support, as well as a source of water and nutrients. We will need to understand the relevant processes. As our information becomes more mechanistic, we should find it harder to separate the study of forest soil science from cropland systems because the difference is the dominance of different sets of processes working in a different management timescale. As our forests are considered a source of wood and pulp products as well as water, wildlife, and recreation, forest soil science will continue to contribute to both the knowledge base and the management of these natural renewable resources.

Forest Soils: Calcium Depletion

Tom G. Huntington

U.S. Geological Survey (USGS), Augusta, Maine, U.S.A.

Abstract

Calcium (Ca) depletion in forest soils is a natural pedogenic process that can be accelerated by harvest removals and acidic deposition. Several lines of evidence support the fact that Ca depletion is an ongoing process in many forest soils. Direct remeasurements have shown Ca depletion in the Eastern United States and Europe. Mass balance studies strongly suggest that outputs exceed inputs in many intensively studied forest catchments. Indirect evidence from strontium isotope analysis, stem wood chemistry, fertilization experiments, and other studies is also consistent with ongoing Ca depletion. Ca depletion is a threat to forest ecosystems because decreases in Ca in soils can ultimately adversely influence health and vigor of sensitive trees, fish, snails, birds, and mollusks. Depletion is also a threat because it can delay forest and associated aquatic ecosystem recovery following reductions in emission and deposition of acidic compounds.

INTRODUCTION

Calcium (Ca) depletion in forest soils is the process by which Ca stored in the soil in exchangeable, organic, and mineral-bound forms is gradually lost in response to natural and anthropogenic mechanisms. The primary natural mechanism is the weathering of soil minerals and leaching of dissolved Ca to ground and surface water. The primary anthropogenic mechanisms are removal of Ca in forest products and the acceleration of leaching losses by elevated atmospheric acidic deposition.^[1,2] When the rate of Ca losses through leaching and harvest removals exceeds the rate of replenishment through atmospheric deposition and the weathering of primary minerals, soil Ca is depleted. These input and output processes are shown schematically in Fig. 1. Ca depletion results in decreased Ca availability to plants and lower Ca concentrations in soil, surface, and ground water.

WHAT IS THE EVIDENCE FOR CA DEPLETION?

There is a growing body of evidence that supports the hypothesis that forest soils in the Eastern United States and Europe are experiencing Ca depletion. The evidence can be grouped into three major categories: 1) direct remeasurements over time; 2) mass balance studies; and 3) indirect evidence that is consistent with decreasing Ca. Several studies in Europe^[3–5] and the United States^[6–9] have found significant decreases in exchangeable Ca in forest soil following decades of acidic deposition and uptake by aggrading forests. These remeasurement studies are the most direct evidence that forest soils in many regions are experiencing net Ca depletion.

Many studies have measured the input and output fluxes of Ca in forest ecosystems and concluded that the rates of

loss substantially exceed inputs.^[10–13] Examples of pools and fluxes of Ca determined in biogeochemical studies of this kind are summarized in Table 1. In these studies, investigators have attempted to measure atmospheric inputs, vegetation uptake, and soil leaching losses over a period of several years to determine average annual rates. The rate of weathering is usually estimated indirectly. There is more uncertainty in the weathering estimate than in other estimates, but it can frequently be constrained using silica export of strontium isotope ratios. The balance of evidence from the majority of intensively studied sites indicates that Ca outputs exceed inputs. The potential for weathering resupply is an important uncertainty, but the weight of evidence suggests that declines in Ca reserves in forest ecosystems are ongoing, arguing that weathering rates are too slow to replenish Ca.^[13,19]

There have also been a substantial number of studies that have provided insight into the status of forest soil Ca using indirect evidence. Strontium isotope ratio analysis has been used to infer ongoing Ca depletion in the Northeastern United States.^[20,21] Trends in stem wood chemistry have also been shown to be consistent with Ca depletion in red spruce dominated forests of the Northeastern United States.^[22,23] Studies have also reported that the failure of stream water to recover from acidification despite large reductions in sulfur deposition is indicative of Ca depletion.^[24]

Long-term trends in stream water chemistry and sulfate deposition at several forested watersheds at the Coweeta Hydrologic Laboratory in North Carolina and in the Shenandoah National Park in Virginia support the hypothesis that soil retention of atmospherically derived sulfate has decreased in years^[25,26] supporting the mechanism for ongoing Ca depletion.^[1,2] Many streams in the Eastern United States have experienced statistically significant decreases in Ca concentrations that may be related to soil

Fig. 1 Ca cycling in forest ecosystems. Inputs to the available pool of exchangeable soil Ca result from atmospheric deposition in precipitation and dust and the weathering of primary minerals. Outputs from this pool result from plant uptake and removal of wood products and leaching from the soil to streams.

depletion.^[10] Other studies have demonstrated positive responses in soil and tree health and vigor following fertilization with Ca suggesting that Ca was a limiting nutrient at these forest sites.^[27–29]

WHY IS CA DEPLETION A THREAT TO FOREST ECOSYSTEMS?

Ca depletion has been implicated in the failure of stream water alkalinity to recover in spite of significant decreases in acidic deposition.^[19,30,31] Decreases in Ca availability have been suggested as factors influencing health and vigor of fish,^[32] snails,^[33] birds,^[34] and mollusks.^[35] Ca depletion is of concern for a variety of reasons related to the many critical roles that Ca plays in tree physiology and the likelihood that Ca limitation will adversely influence many aspects of forest function.^[36] Ca limitation in forest ecosystems is thought to adversely influence disease resistance, wound repair, frost hardiness, and lignin synthesis in trees.^[36] Ca depletion is considered to be an especially serious threat to tropical forests growing on highly weathered soils in the tropics.^[17]

CONCLUSION

Ca depletion in forest soils is a natural pedogenic process that can be accelerated by harvest removals and acidic deposition. Several lines of evidence support the fact that Ca depletion is an ongoing process in many forest soils. Direct remeasurements have shown Ca depletion in the Eastern United States and Europe. Mass balance studies strongly suggest outputs exceed inputs in many intensively studied forest catchments. Indirect evidence from strontium isotope analysis, stem wood chemistry, fertilization experiments, and other studies is also consistent with ongoing Ca depletion. Ca depletion is a threat to forest ecosystems because decreases in Ca in soils can ultimately adversely influence

health and vigor of sensitive trees, fish, snails, birds, and mollusks. Ca depletion is also a threat because it can delay forest and associated aquatic ecosystem recovery following reductions in emission and deposition of acidic compounds.

Forest Soils: Major

Ken Van Rees

Department of Soil Science, University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Abstract

Soils vary around the world and reflect the types of vegetation and other soil-forming factors and processes that have been acting upon them. Soils are much younger and less developed in boreal forests compared to those soils associated with tropical forests. Regardless of the degree of soil development, forest soils will continue to play an important role in ecosystem function.

INTRODUCTION

Soil is defined as the unconsolidated mineral or organic material that occurs at the earth's surface and is capable of supporting plant growth. Forest soils are those soils that have developed underneath forest vegetation.^[1] Forests cover approximately 29% of the world's land surface and play a key role in most ecosystems except for the tundra, deserts, some grasslands, and wetlands. Forests and forest soils contain about 60% of the carbon contained in the earth's land surface and thus are an integral part in the global carbon cycle.^[2] Soil development or genesis beneath forest ecosystems is influenced by a number of different factors. These factors include the type and nature of the forest vegetation, parent material and topography, climate, human or organism influence, and the amount of time that these factors have been influencing soil development.^[3] All these factors combined together can result in soils with different physical, chemical, and biological properties that are unique to those conditions and provide the framework for how soils are classified. Generally, there are two main classification systems used in the world: the U.S. soil taxonomic^[4] and the Food and Organization systems.^[5]

Soils types will vary around the world, but some generalizations can be made based on the major forest biomes that exist. The major forest biomes include boreal and coniferous forests, temperate deciduous/mixed forests, scrub and woodlands, temperate rain forest, tropical rain forests, and tropical monsoon/deciduous forests. A generalized vegetation map of the world showing most of these forest biomes is provided in [Fig. 1](#). Typical soil types associated with these forests are summarized in [Table 1](#) and discussed later for each major forest biome.

BOREAL AND OTHER CONIFEROUS FORESTS

Coniferous forests, otherwise known as boreal forests, are comprised mainly of spruce and pine trees with birch

and poplar appearing at the southern range. These forests, located in the northern hemisphere, extend southward from the tundra tree line and occur across Canada, Europe, and Asia. The soils for these forests are generally acidic and form on sandy deposits from glaciation and range in thickness from >1 m to very shallow (<1 m) underlain by bedrock (Precambrian shield). These forests receive about 90 cm/yr of precipitation or less and have low rates of evapotranspiration, which results in water moving through the soil profile.^[1] Because these forests have adapted to cooler climates, the decomposition of litter material is slow, resulting in thick forest floors compared to other forests as well as the accumulation of mosses and lichens. Soils of the boreal forest are relatively young compared to tropical soils because of glaciation; consequently, there are soils that have little to no development or no distinct soil horizons and are known as Entisols or Regosols. Sandy soils that have undergone more soil development, such as the development of a reddish colored B horizon, are called Inceptisols and are associated with pine forests growing on outwash plains. More soil development can result when organic acids that are released from slowly decomposing litter material bind with iron (Fe) and aluminum (Al) in the soil causing them to be leached deeper into the soil profile. This process is called podzolization and results in the development of a dark-colored B or spodic horizon (the accumulation of Fe, Al, and organic matter), which belongs to the Spodosol or Podzol soil groups. Often these soil profiles have a bleached-looking (light gray) surface horizon (E or Ae horizon) underlain by a darker colored (reddish brown) spodic horizon. Boreal forests also have extensive low-lying areas in the landscape that have high water tables resulting in organic soils known as Histisols or organic soils. These organic layers can be thicker than 40 cm and in some cases are few meters thick. These soils are generally unproductive for tree growth but are still important for wildlife and water quality.

Fig. 1 World map of major vegetation types.
Source: From Murai, Honda, et al.^[6]

TEMPERATE DECIDUOUS FORESTS

Temperate deciduous forests are found in North America, Europe, and China and are comprised of oaks, beech, ash, maple, basswood, and yellow-poplar trees. These forests occur on a wide diversity of parent materials, but the soils are generally mildly acidic. Spodosols are common under oak/birch forests in Western Europe. In Central Europe and China, forests have developed on more neutral, clayey Mollisols or chernozemic soils, which are characterized by a surface mineral horizon containing high amounts of well-decomposed organic matter. This surface horizon enriched with organic matter makes these soils very productive for tree growth, and the accumulation of organic matter is believed to have originated from grassland conditions. In North America, deciduous forests have

developed on Alfisols in the north and on Ultisols in the south. Alfisols develop in cool to warm humid climates and are characterized by an accumulation of clay in the subsurface. This clay was eluviated or transported from upper horizons and deposited or illuviated in the B horizon to form an argillic horizon. These argillic horizons have more than 35% of their cation exchange sites saturated with bases such as calcium (Ca) and magnesium.^[3] The degree of soil development for Alfisols is greater than that for Inceptisols but less than that for Spodosols. Ultisols are similar to Alfisols in that they have developed an argillic horizon; however, Ultisols develop in more humid tropical areas with greater precipitation, resulting in more weathering and thus <35% base cations with more acidic conditions compared to Alfisols. Subsurface horizons in Ultisols tend to be redder in color, indicating an accumulation of Fe oxides, and are less productive than Alfisols.

Mixed forests are transition forests between boreal and deciduous forests. Mixed forests of aspen/spruce or birch, maple, and oaks growing with conifers occur in the northern hemisphere. In the southern hemisphere in Chile, Southern Brazil, South Africa, and New Zealand, one can also find mixed forests of broad-leaved evergreens and conifers. These forests will occur on Mollisols, Inceptisols, and Alfisols.

Table 1 Soil types associated with the major forest biomes of the world.

Major forest biomes	Area (ha × 10 ⁸)	Soil orders
Boreal and other coniferous forests	18.1	Spodosols, Histisols, Inceptisols, Entisols, and Gelisols
Temperate deciduous forests	11	Spodosols, Alfisols, Mollisols, and Ultisols
Temperate rain forests	3.2	Spodosols, Alfisols, Inceptisols, and Ultisols
Shrub and woodland	8.5	Aridisols, Mollisols, and Alfisols
Tropical rain forests	17.4	Ultisols, Inceptisols, and Oxisols
Tropical monsoon/deciduous forests	4.6	Ultisols and Oxisols

Source: From Landsberg & Gower,^[2] Pritchett & Fisher,^[7] and Waring & Schlesinger.^[8]

TEMPERATE RAIN FORESTS

Temperate rain forests consisting of conifers are located on the northwest coast of North America and broad-leaved evergreens in southern New Zealand, Chile, and southeastern Australia. These areas have milder, marine climates with relatively higher rainfalls. Spruce, cedar, hemlock, Douglas fir, and redwoods are the dominant species in North America, whereas beech and eucalyptus are found in the southern hemisphere. These forests have thick forest

floors, and soil types range from Spodosols and Inceptisols to Alfisols and Ultisols. These forests are highly productive and produce rather tall and large trees.

SHRUB AND WOODLAND

These forests are limited by the amount of rainfall and are less productive than most forests in the world. They range from sclerophyllous communities with Mediterranean-type climates to xerophytic shrublands where droughts can persist throughout the year.^[8] The sclerophyllous communities consisting of evergreen oaks or eucalyptus species are located in southwestern North America, Australia, Chile, South Africa, and Mediterranean regions. The xerophytic shrublands (oaks, pinyon, and ponderosa pines) are located in the interior of the Southwestern United States, Central Australia, Eurasia, southern Sahara, and the western regions of the Andes in central and southern South America. Soils that have developed under these conditions range from Mollisols and Alfisols to Aridisols. Aridisols, also known as dry soils, are common when evapotranspiration exceeds precipitation inputs, resulting in the accumulations of Ca carbonate, gypsum, soluble salts, or exchangeable sodium in the soil profile. The accumulation of soluble salts makes these soils more alkaline which are termed saline soils; however, if there are high concentrations of sodium on the exchange sites, these soils are classified as sodic soils, which can disperse organic matter and clay resulting in a black surface crust.^[3]

TROPICAL RAIN FORESTS

There are three distinct tropical rain forests in the world—the American, African, and Indo-Malaysian.^[1] These evergreen forests have high air temperatures and humidity, resulting in rapid decomposition of the forest floor, which is the opposite of that seen for boreal forests. Higher precipitation in these areas results in highly weathered soils, with soil development occurring deeper in the soil profile. The range of soil types is quite variable under tropical forests, and they have been studied less than temperate forests. Soils range from Inceptisols and Ultisols to Oxisols and Andisols. Oxisols are the oldest and hence most weathered soils, with intense leaching that removes a large part of the silica from silicate materials, resulting in more 1:1 type silicate clays or non-expanding clays. The sub-surface horizon characteristic of Oxisols is the oxic

horizon, which is very high in clay particles dominated with oxides of Fe and Al.^[3]

TROPICAL MONSOON/DECIDUOUS FORESTS

Tropical monsoon forests experience significant seasonal droughts (5 mo with <9 cm of rain) and are dominated by seasonal deciduous trees such as teak. These forests are found in Central and South America, Indo-Malaysia, and Africa, with the largest area of tropical deciduous forests located in Southeastern Asia. The soils are not as highly weathered as tropical rain forests but consist of soils from the Ultisols and Oxisols orders.

CONCLUSION

Soils vary around the world and reflect the types of vegetation and other soil-forming factors/processes that have been acting upon them. Soils are much younger and less developed in boreal forests compared to the soils associated with tropical forests. Regardless of the degree of soil development, forest soils will continue to play an important role in ecosystem function.

Forest Soils: Nutrient Cycling

Neil W. Foster

Natural Resources Canada, Sault Ste. Marie, Ontario, Canada

Jagtar S. Bhatti

Canadian Forest Service, Northern Forestry Centre, Edmonton, Alberta, Canada

Abstract

Nutrient cycling in forest ecosystems is controlled primarily by the following four key factors: climate, site, abiotic properties (topography and parent material), and biotic communities. The role of each factor in ecosystem nutrient dynamics is discussed and illustrated with selected examples from boreal, temperate, and tropical zones. The importance of ecosystem disturbance to nutrient cycling is examined briefly, since some nutrients are added or lost from forest ecosystems through natural (e.g., fire, erosion, and leaching) or human activity (harvesting and fertilization).

INTRODUCTION

Nutrients are elements or compounds that are essential for the growth and survival of plants. Plants require large amounts of nutrients such as nitrogen (N), phosphorus (P), carbon (C), hydrogen, oxygen, potassium (K), calcium, and magnesium (Mg) but only small amounts of others such as boron, manganese, iron (Fe), copper, zinc, and chlorine (micronutrients). Forest nutrient cycling is defined as the exchange of elements between the living and non-living components of an ecosystem.^[1] The processes of the forest nutrient cycle include nutrient uptake and storage in vegetation perennial tissues, litter production, litter decomposition, nutrient transformations by soil fauna and flora, nutrient inputs from the atmosphere and the weathering of primary minerals, and nutrient export from the soil by leaching and gaseous transfers.

Each nutrient element is characterized by a unique biogeochemical cycle. Some of the key features of the major nutrients are presented in [Table 1](#). Forest trees make less demand on the soil for nutrients than annual crops because a large proportion of absorbed nutrients are returned annually to the soil in leaf and fine root litter and are reabsorbed after biological breakdown of litter materials. Also, a large portion of nutrient requirement of trees are met through internal cycling as compared with agricultural crops.

INFLUENCE OF CLIMATE

Large-scale patterns in terrestrial primary productivity have been explained by climatic variables. In aboveground vegetation, nutrient storage generally increases in the following order: boreal < temperate < tropical forests ([Table 2](#)). In contrast, forest floor nutrient content and residence time

increase from tropical to boreal forests, as a result of slower decomposition in the cold conditions of higher latitudes.

In subarctic woodland soils and Alaskan taiga forests, nutrient cycling rates are low because of extreme environmental conditions.^[2] Arctic and subarctic forest ecosystems have lower rates of nutrient turnover and primary production because of low soil temperature, a short growing season, low net actual evapotranspiration (AET), and the occurrence of permafrost. Low temperature reduces microbial activity, litter decomposition rates, and nutrient availability and increases C accumulation in soil.

In contrast with high latitudes, conditions in a tropical forest favor microbial activity throughout the year, which generally results in faster decomposition except in situations with periodic flooding, soil desiccation, and low litter quality.^[3] Rates of plant material decay are an order of magnitude higher in tropical soils than in subarctic woodland soils. The low storage of C and high amount of litter production in highly productive tropical forests contrast with the high C storage and low litter production in boreal forests ([Table 2](#)).

INFLUENCE OF BIOTIC FACTORS

Nutrient cycles are modified substantially by tree species-specific controls over resource use efficiency (nutrient use per unit net primary production). Species vary widely in their inherent nutrient requirements and use.^[4] These effects can be split into the following two categories: the accumulation into living phytomass and the production of various types of nutrient-containing dead phytomass. Rapid accumulation of phytomass is associated with a net movement of nutrients from soil to vegetation. More than half of the annual nutrient uptake by a forest is typically returned

Table 1 Features of the major nutrient cycles.

Element	Uptake by the trees	Major sources for tree uptake	Limiting situations
Carbon	Atmosphere	Atmosphere	Atmospheric concentration may limit growth
Oxygen	Atmosphere	Atmosphere	Waterlogged soils
Hydrogen	Atmosphere	Atmosphere	Extremely acidic and alkaline conditions
Nitrogen	Soluble NO ₃ and NH ₄ ; N ₂ for N-fixing species	Soil organic matter; atmospheric N ₂ for N-fixing species	Most temperate forests, many boreal forests, and some tropical forests
Phosphorus	Soluble P	Soil organic matter; adsorbed phosphate and mineral P	Old soils high in Fe and aluminum, common in subtropical and tropical environment
Potassium, calcium, and magnesium	Soluble K ⁺ /soluble Ca ²⁺ /soluble Mg ²⁺	Soil organic matter; exchange complex and minerals	Miscellaneous situations and some old soils

to forest floor (litterfall) and soil (fine root turnover). The subsequent recycling of these nutrients is a major source of available nutrients for forest vegetation. The mean annual litterfall from aboveground vegetation increases from boreal regions to the tropics following the gradient of productivity (Table 2).

Table 2 Nutrient distribution in different forest ecosystems.

	Vegetation (Mg ha ⁻¹)	Forest floor (Mg ha ⁻¹)	Soil (Mg ha ⁻¹)	Residence time (year)
Carbon				
Boreal coniferous	78–93	37–113	41–207	800
Temperate deciduous	103–367	42–105	185–223	200
Tropical rain forest	332–359	7–72	2–188	120
Nitrogen				
Boreal coniferous	0.3–0.5	0.6–1.1	0.7–2.87	200
Temperate deciduous	0.1–1.2	0.2–1.0	2.0–9.45	6
Tropical rain forest	1.0–4.0	0.03–0.05	5.0–19.2	0.6
Phosphorus				
Boreal coniferous	0.033–0.060	0.075–0.15	0.04–1.06	300
Temperate deciduous	0.06–0.08	0.20–0.10	0.91–1.68	6
Tropical rain forest	0.2–0.3	0.001–0.005	0.06–7.2	0.6
Potassium				
Boreal coniferous	0.15–0.35	0.3–0.75	0.07–0.8	100
Temperate deciduous	0.3–0.6	0.050–0.15	0.01–38	1
Tropical rain forest	2.0–3.5	0.020–0.040	0.05–7.1	0.2

Nutrient availability is strongly influenced by the quantity and quality of litter produced in a forest. A high proportion of the variation in foliar N concentrations at the continental scale has been explained by differences between forest types, which in turn have large impact on litter quality and the nutrient content of forest floors. In many temperate and boreal forest ecosystems, microbial requirement for N increases or decreases with labile supplies of soil C. Increased microbial demand for N may temporarily decrease the N availability to trees during the initial decomposition of forest residues with a wide C/N ratio. Microbes immobilize N from the surrounding soil, relatively rapid for readily decomposable organic matter (needle litter) and more slowly for recalcitrant material (branches and boles).

Rates of net N mineralization are higher, and the retention of foliar N is lower in temperate and tropical than in boreal forest soils. The N limitation of productivity, therefore, is weak in tropical forests and increases from temperate to boreal and tundra forest systems. Trees may obtain organic N and P from the soil via mycorrhizae or by relocation from older foliage prior to abscission and, thereby, partly reduce their dependence on soil as a source of inorganic nutrients. Increased understanding of the fundamental relationships between soil properties and plant nutrients requirements will most likely come from the examination of plant–fauna–microbe interactions at root surfaces (rhizosphere), rather than in the bulk soil.

INFLUENCE OF ABIOTIC FACTORS

Forests have distinctive physiographic, floristic, and edaphic characteristics that vary predictably across the landscape within a climatically homogeneous region. Differences in the elemental content of parent material influence the tree species composition between and within a landscape unit. For example, wind deposited soils, which support hardwood or mixed wood forest, are likely to be fine textured with high nutrient supplying capacity. In contrast, outwash sands that often support pine forests are coarse textured and infertile.

Heterogeneity within the landscape results in sites differing in microclimatic conditions and physical and chemical properties, which produce different geochemical reaction rates and pools of available nutrients in soil. Soil type and topographic-microclimate interactions are important feedback that influence biological processes, such as the rate of N mineralization in soil. Low P availability is a characteristic of geomorphically old, highly weathered tropical, subtropical, and warm temperate soils.^[3] The type and age of parent material from which the soil is derived can influence the base status and nutrient levels in soil. Soils in glaciated regions are relatively young and rich in weatherable minerals. Mineral weathering is an important source of most nutrients for plant uptake, with the exception of N. Nutrient availability is regulated by the balance between weathering of soil minerals and precipitation, adsorption, and fixation reactions in soil.

Edaphic conditions can exert a strong influence on forest productivity and produce considerable variation in nutrient cycling processes. Soils with low N, P, or pH support trees with low litter quality (high in lignin and tannins that bind N) that decomposes slowly. Edaphic limitations on growth may be compensated by an increase in rooting density and depth. Some late-succession or tolerant species have a shallower root distribution relative to intolerant pioneer species and are adapted to sites where nutrients and moisture are concentrated at the soil surface. In contrast, nutrient uptake from subsoil horizons is more important in highly weathered warm temperate soils where nutrient depletion takes place deeper in the soil.

ROLE OF DISTURBANCE

Disturbances such as fire, harvesting, hurricanes, or pests affect nutrient cycling long after the event. In fire-dominated ecosystems, intensive wildfire results in a horizontal and vertical redistribution of ecosystem nutrients. Redistribution results from the combined effects of the following processes: 1) the oxidation and volatilization of live and decomposing plant material; 2) the convection of ash particles in fire generated winds; 3) the water erosion of surface soils; and 4) the percolation of solutes through and out of the soil. The relative importance of these processes varies with each nutrient and is modified by differences in fire intensity, soil characteristics, topography, and climatic patterns. Expressed as a percentage of the amount present in vegetation and litter before fire, the changes often follow the given order:

$$N > K > Mg > Ca > P$$

Harvesting removes nutrients from the site and interrupts nutrient cycling temporarily. The recovery of the nutrient

cycle from harvest disturbance is dependent partly on the rate of re-establishment of trees and competing vegetation. Re-vegetation may occur within months in the tropics, 2–5 years in temperate regions, and longer in boreal and tundra regions.^[5] Recovery assumes that the soil's ability to supply nutrients to plant roots has not been altered by disturbance. If nutrients cannot be supplied by the soil at rates sufficient to at least maintain the rate of growth of the previous forest, then fertilization may be necessary to maintain site productivity.

Nutrient cycling and the impacts of disturbance on nutrient cycling have been examined thoroughly in many representative world forests. The impact of natural disturbances and management practices on nutrient cycling processes is generally characterized of the stand or occasionally on a watershed basis. There is a growing demand from policy makers and forest managers for spatial estimates on nutrient cycling at local, regional, and national scales.

The availability of N, P, and K in soil largely determines the leaf area, photosynthetic rate, and net primary production of forest ecosystems. Forest management practices that produce physical and chemical changes in the soil that accentuate the cycle of nutrients between soil and trees may increase forest productivity. Clear-cut harvesting and site preparation practices (mechanical disturbance and slash burning) remove nutrients from soil in tree components and by increased surface runoff, soil erosion, and off-site movement of nutrients in dissolved form or in sediment transport. In the tropics, potential negative impacts associated with complete forest removal and slash burning are the greatest because a larger proportion of site nutrients are contained in the living biomass. Environmental impacts associated with clear-cutting and forest management in general are confounded by climatic, topographic, soil, and vegetation diversity associated with the world's forests. Best forest management practices can be utilized to control negative impacts on nutrient cycling.

Forest Soils: Properties and Site Productivity

Paul A. Arp

Faculty of Forestry and Environmental Management, University of New Brunswick, Fredericton, New Brunswick, Canada

Helmut H. Krause

University of New Brunswick, Fredericton, New Brunswick, Canada

Abstract

Forest growth restrictions occur on soils with nutrient-poor parent materials, inefficient water and nutrient storage and retrieval capacities, unfavorable pH, low soil organic matter contents, and extreme texture (sand and clay). Some of these soil restrictions can—in part—be corrected by silvicultural means such as change of forest cover type, control of stand density, fertilization, irrigation, and artificial drainage.

INTRODUCTION

Site productivity is a key variable in forest management and yield: it depends on site quality—the inherent capability of the site to produce—and on management input.^[1] Site quality—in turn—is largely determined by soil, topography, and climate. Maximum production occurs when macronutrients [e.g., nitrogen (N), phosphorus (P), potassium (K), calcium (Ca), magnesium (Mg), and sulfur] and micronutrients [e.g., zinc (Zn), boron (B), and copper (Cu)] are consumed in certain amounts and proportions to each other for every unit of biomass produced, soil moisture and nutrients are available in sufficient quantities, and an extensive root system exists for efficient water and nutrient uptake. Related soil and site research throughout the world^[2] have, inter alia, produced simple guidelines for interpretations of soil survey data and complex site classification systems based on climate, geology, and soil properties.^[3]

In practice, the site index (SI = average height of dominant trees in a stand at a certain reference age, e.g., 50 years) is a local measure of site quality. This index is presumed to integrate the effects of climate, topography, and soil. Unfortunately, SI also varies with stand history, stocking level, and species composition. Soil properties that affect site quality and, therefore, forest growth and ecosystem functioning are highlighted in [Table 1](#). Examples of soils with contrasting productivity are shown in [Fig. 1](#).

INFLUENCE OF SOIL PHYSICAL PROPERTIES

Highest site productivity generally occurs on deep, friable, and organically enriched soils with well-functioning root systems. In other soils, root growth is often restricted by, e.g., mechanical impedance, lack of aeration, low

temperature, and/or the presence of toxic substances. Aside from shallow bedrock, roots encounter mechanical impedance in soils with high soil strength. High soil strength arises naturally in hardpans and fragipans, beneath the plough layer on old fields and on soils that may have been compacted by logging equipment. In such cases, tree growth generally decreases with decreasing depth of root-permeable soil. In mineral soils, roots usually encounter mechanical impedance at bulk density values of 1.3–1.75 Mg m⁻³, depending mainly on texture.

SOIL MOISTURE

A crucial requirement to maximize site utilization is the soil's ability to store water to compensate for precipitation deficits during periods of high evapotranspiration.^[4] For example, annual basal area increments of southern pines were shown to increase directly with number of days of adequate soil water quality. Available water is customarily estimated as the difference between the field capacity and the permanent wilting point of the root-accessible portion of each soil. These parameters—in turn—are primarily determined by soil texture and organic matter.

SOIL AERATION

Good air supply is essential for good root growth.^[5] Insufficient aeration occurs in soils with high water tables and in fine-textured, structureless soils that are water-saturated throughout most of the growing season. Insufficient aeration is usually indicated by gleyed and mottled soil layers. Most tree roots do not penetrate such soil layers. However, some species are tolerant of low soil aeration. For example, Douglas fir does not tolerate low soil

Table 1 Soil properties related to site quality.

Soil property	Relation to site quality	Optimal conditions
Mineralogical composition of parent material	Affects K, Mg, and Ca supply	Abundance of dark (mafic) minerals
pH	Affects nutrient availability	5–7
SOM content	Source of N and P, promotes structure	Presence of forest floor, accumulations in A and B horizons
Texture	Affects drainage, water, and nutrient storage	Sandy loam, loam, silt loam ^a
Structure	Promotes aeration, counteracts compaction, and high soil strength	Granular ^a
Consistency	Affects soil strength	Friable ^a
Drainage	Determines soil moisture regime and aeration status	Well and moderately well drained ^a
Depth of A horizon	Location of high biological activity and nutrient availability	>10 cm
Stone content	Improves thermal regime, limits soil volume for rooting	<15%
Depth to least permeable horizon	Delimits rooting space, improves moisture regime in coarse soils	> 80 cm
Depth to mottling	Reveals presence of excess water and lack of aeration	> 75 cm
Thickness of B horizon	Clay, SOM, and nutrient enriched zone	> 30 cm

^aClasses as defined in Agriculture Canada Expert Committee on Soil Survey, 1987. The Canadian System of Soil Classification.

Fig. 1 Soils with contrasting productivity in the Atlantic Region of Northeastern North America. Left: brunisolic Podsol supporting vigorous forest of northern tolerant hardwoods. Right: gleyed Podsol supporting a pure black spruce stand. Note uniformly brown color, structure (granular to subangular blocky), and abundance of roots throughout.

aeration, but red alder, western cedar, sitka spruce, and western hemlock are adapted to shallow water tables.^[1] Controlled drainage to remove excess water often improves productivity and postdisturbance tree regeneration, especially when the roots continue to be constantly supplied with water by way of capillary rise from the water table below, as is often the case for sandy soils.^[6] On fine-textured soils, however, this benefit might not occur because the same capillary rise may reduce soil aeration.

SOIL TEMPERATURE

Soil temperature is an important parameter because it influences root growth and microbial activities, which—in turn—influence soil organic matter (SOM) decomposition and nutrient availability. Literature values for minimal (0–7°C) and optimal (10–25°C) soil temperatures vary over wide ranges, thereby reflecting the climatic adaptation of species. Soil temperatures generally decrease with increasing elevation and latitude and are generally lower under coniferous forests than deciduous forests: dense conifer canopies intercept much of the incoming solar radiation, thereby reducing the solar heating of the soils underneath, especially of wet soils. Delayed soil heating often implies delayed root growth, thereby shortening the effective growing season and hence forest growth. Fine roots are also sensitive to soil acidification:^[7] slowly soluble soil aluminum (Al) may convert to toxicologically active Al as the forest soil acidifies either naturally during the course of their development or on account of acid deposition.

INFLUENCE OF NUTRIENT SUPPLIES AND AVAILABILITIES

Matters dealing with nutrient supplies, retention, and availability are of particular importance to sustainable forest production as follows:

1. Long-term nutrient supplies of forest ecosystems need to be sustainable in principle. Additions of nutrients to each site come from external sources (atmospheric accretions, liming, and fertilizer) and from internal sources (weathering of primary soil minerals, biochemical cycling). Under natural conditions, origin and type of soil parent material are strong determinants of rate of weathering and related nutrient supplies.
2. Nutrient retention and release involve numerous reactions, including ion sorption and desorption on mineral and organic colloids; precipitation by metal oxides; complexation by humic substances; immobilization of nutrient ions by microorganisms; and SOM mineralization. All these processes are influenced by soil texture, SOM content, cation exchange capacity

(CEC), pH, base saturation, aeration, and prevailing soil temperature and moisture regimes.

3. Nutrient availability results from the net cumulative difference between supplies, immobilization, leaching, mineralization, and past uptake and is also controlled by chemical equilibria. Potential fertility of a soil can provisionally be appraised from simple field observations. For example, favorable contents and distribution of SOM and clay imply improved N, P, and base cation supply, and the presence of black minerals in the parent material may indicate K and Mg sufficiency. To be reliable, such observations must be supplemented by appropriate soil analysis.

The effect of soil parent material, via the continuing weathering of primary minerals, is often reflected in the species composition of natural forests. For example, in central regions of eastern North America, soils derived from calcareous shales often support, e.g., basswood, white ash, yellow-poplar, and hickory, while soils derived from acid sedimentary rocks support high percentages of beech, yellow birch, red maple, and certain oaks. As well, white cedar and eastern red cedar grow better on calcareous soils than on acid soils. In Sweden, site productivity is grouped by Ca content of the soil parent material: soils derived from Ca-poor substrates commonly support Scots pine at low productivity; soils with intermediate Ca availability support pine and mixed conifer forests with high productivity; and soils derived from basic igneous sedimentary substrates support productive stands of Norway spruce and hardwoods.

CA, MG, K, P, AND TRACE ELEMENTS

In areas where soils are very old and deeply weathered (e.g., tropical and subtropical regions in Africa, Asia, Australia, and Central and South America) or where soils have been heavily cropped, forest productivity is often limited because of limited supplies of Ca, Mg, K, P, and/or micronutrients such as Zn, Cu, and B.^[8] Such soils often consist of abundant accumulation of Al and iron (Fe) sesquioxides, which typically produce soils with high anion exchange capacities (AEC) but low CEC. As a result, nutrient elements such as K, Mg, and Ca are generally in short supply and severe losses of forest productivity are likely to occur when such soils are stripped of their natural forest vegetation. Such soils, furthermore, may lose their originally friable consistency with gradual SOM loss and become cementation when exposed to air and allowed to dry.

Areas that have been covered by glaciers and have a temperate to boreal climate can support productive forests set within the limits set by climate and soil depth. This can be attributed to the continuing release of Ca, Mg, K, and P through natural weathering of the ground-up bedrock (till). Soils in these areas generally have low accumulations of Fe

and Al sesquioxides, except in areas of high soil acidity where forest productivity may decrease as a result of advanced podsolization, i.e., the formation of Fe and organic matter cemented hardpans within the B horizon. Except for N, mineral deficiencies are infrequently encountered in these areas.

N AVAILABILITY

In boreal and subboreal climates, forest productivity is commonly restricted by low N availability, which is the result of slow SOM turnover rates. Under these conditions, the forest floor is the principal source of available N: the A horizon is—more often than not—strongly leached, poorly developed or absent, and N in the B layers is essentially unavailable. In these soils, N availability is further adversely affected by high soil acidity, impeded drainage, and restricted soil aeration. In contrast, soils with mesic or warmer temperature regimes have SOM-enriched A layers with high levels of available N. As shown in many studies,^[2] site quality on these soils rises with increasing depth of the A layer.

CONCLUSION

Forest growth restrictions occur on soils with nutrient-poor parent materials, inefficient water and nutrient storage and retrieval capacities, unfavorable pH, low SOM contents, and extreme texture (sand and clay). Some of these soil restrictions can—in part—be corrected by silvicultural means such as change of forest cover type, control of stand density, fertilization, irrigation, and artificial drainage. All of these growth restrictions have been considered in efforts to develop soil quality indices for monitoring sustainability of forest management

practices.^[9] Additional efforts are being made to quantify the relationships between soil and forest production by way of modeling.^[10,11]

Freeze and Thaw: Diurnal

Joseph L. Pikul

Northern Grain Insect Research Lab (NGIRL), U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Brookings, South Dakota, U.S.A.

Abstract

Diurnal freezing and thawing of soils are a worldwide phenomenon impacting many biological and physical aspects of agricultural soils. Available management options to reduce soil-freezing events may be limited to manipulation of crop residues. Surface cover creates a unique microclimate, affording thermal protection to soil and thereby reducing the incidence and severity of frozen soil. The reduction of soil-freezing events could be expected to reduce soil water evaporation, soil surface crusting, and undesirable movement of agricultural chemicals.

INTRODUCTION

In northern climates throughout the world, periodic freezing and thawing of soil are common. Sharratt et al.^[1] estimated that approximately 30% of the earth's landmass is periodically frozen, and that an additional 20% of the landmass is underlain by permafrost. Some of the world's most productive soil lies within regions where soil may be seasonally or diurnally frozen. Freezing and thawing of soil exert a profound effect on soil water distribution, solute movement, soil physical and chemical condition, biological processes, and hydrology.^[1–4] There are few land-management options available to lessen the effect of freezing weather on the soil thermal environment. However, maintaining surface cover can reduce the incidence and penetration depth of frozen soil^[5] on croplands. This entry discusses the diurnal soil freeze–thaw and soil–water movement associated with night-time radiative freezing of the soil surface.

SOIL FREEZING AND WATER MOVEMENT

Nocturnal soil freezing and daytime thawing cycles are numerous in late autumn and early spring.^[6] About 100 diurnal freezing and thawing cycles, recorded at a 1-cm depth, have been observed in a year in mountain regions.^[7]

Night-time freezing, termed *radiation frost*,^[8] is a consequence of rapid loss of long-wave radiation from the earth to the atmosphere on cloudless nights.

When moist soil begins to freeze, as during a radiation frost, water migrates upward to the freezing front (surface) and is held there as ice. During subsequent daytime thaw, near-saturated soil conditions may develop at the surface.^[9] Differences in soil water

potential within the soil profile are responsible for water movement within soil. Water moves from regions of high water potential (wet soil) to low water potential (dry soil). How fast water moves within soil depends on the water potential gradient (driving force) and the ability of soil to transmit water (hydraulic conductivity). In the case of soil freezing, very large water potential gradients develop as a consequence of rather small temperature gradients.

As the surface cools and soil temperature dips below 0°C, a fraction of the water freezes within the soil pores.^[10] Ice particles remain separated from solid particles by a film of water; the thickness of which depends upon temperature, pore size distribution, solutes in pore water, and freezing and thawing history.^[11] Ice formation in soil pores effectually dries the soil and results in a reduction of water potential. A water potential gradient is then established across the freezing front, creating the conditions whereby water flows from unfrozen soil toward the freezing front. Water flows toward the region of low potential.

Repeated saturation and subsequent drying of the soil surface, as occurs during diurnal freeze and thaw cycles, may accelerate surface crusting. However, the identification of direct consequences of freeze–thaw on soil structural stability is confounded due to soil type, soil water content at freezing, and characteristics of cyclic freezing and thawing.^[12]

FIELD STUDIES

Microenvironment created by the presence or absence of surface residue strongly affects surface energy exchange and, consequently, soil thermal environment. Pikul and Allmaras^[9] revealed effects of crop residue cover on soil

Fig. 1 Water redistribution during one freeze-thaw cycle: (A) soil water content (ice and liquid) of the surface to 0.5-cm depth and (B) soil temperature at 0.25 cm. Soil froze to a depth of 1.5 cm on the bare surface treatment but did not freeze under residue cover.

water movement during consecutive freezing and thawing cycles. Their field studies included both residue-covered and bare plots. Water redistribution during one freeze-thaw cycle described by Pikul and Allmaras^[9] is shown in Fig. 1. The soil did not freeze on plots with residue cover but froze to about 1.5 cm on plots having a bare surface. Soil water content under residue cover remained essentially unchanged throughout the night. On bare plots, soil water content of the surface, 0.5-cm layer (Fig. 1), increased from 0.28 kg/kg at 12:00 P.M. to 0.45 kg/kg at 6:00 A.M. Soil water content includes both liquid and ice. The quantity of water redistributed, as a consequence of soil freezing, depends on soil water content at the onset of soil freezing.^[13] In this example, both the bare surface and residue-covered plots entered the freezing cycle at about the same water content (Fig. 1). Therefore, the sharp increase in soil water on the bare surface plot was a result of steep water potential gradients that developed as a consequence of soil water freezing.

Concurrent with the decrease in soil temperature to below freezing was an increase in soil water content in the bare surface plot (Fig. 1). The onset of soil freezing in the bare surface plot was at 11:30 P.M., and significant water redistribution began shortly thereafter. Minimum soil temperature at 0.25 cm was -0.8°C . Soil temperature in residue-covered plots hovered near 0.0°C during the night (Fig. 1).

SIMULATION STUDIES

Heat and water flow in freezing soil have been modeled using several approaches with varying degrees of complexity. All models require detailed knowledge of

physical, chemical, hydrologic, and thermal properties of the soil. Generally, the most complex models include provisions for frost heave and overburden pressures.^[14] However, heat and water flow during daily freeze and thaw cycles have been successfully simulated by excluding frost heave.^[15] Cary^[16] provided an example of a simulation model that included solute transport and frost heave. The Simultaneous Heat and Water model,^[17] one of the more detailed models of snowmelt and soil freezing, has been used to simulate soil freezing, thawing, snowmelt, and water runoff.

CONCLUSION

Diurnal freezing and thawing of soils are a worldwide phenomenon impacting many biological and physical aspects of agricultural soils. Available management options to reduce soil-freezing events may be limited to manipulation of crop residues. Surface cover creates a unique microclimate, affording thermal protection to soil and thereby reducing the incidence and severity of frozen soil. The reduction of soil-freezing events could be expected to reduce soil water evaporation, soil surface crusting, and undesirable movement of agricultural chemicals.

Frozen Soils: Water Relations

John M. Baker

U.S. Department of Agriculture—Agriculture Research Service (USDA-ARS),
St. Paul, Minnesota, U.S.A.

Abstract

Heat and water relations in frozen soil are difficult to study. Researchers are hampered by the inability to separately measure water and ice contents at similar spatial scales and by the complications arising from simultaneous, coupled transport of heat and water in a deformable medium. Formal theory describing phase equilibrium in ideal, uniform porous medium is well established but application of that theory to transient phenomena in structured, plastic, soils with complex mineralogy is elusive.

INTRODUCTION

Generally, soils freeze from the surface downward, due to radiative and convective heat loss at the surface. Water contained in soil does not freeze at a single temperature; rather, it freezes gradually over a temperature range. Within this range, water and ice coexist in thermodynamic equilibrium, with the relative proportions of each dependent on temperature, solute content of the water, and retention properties of the medium. As the temperature decreases and more ice is formed, the water potential of the remaining liquid decreases as well. The decline in water potential accompanying freezing creates a gradient favoring water flow toward the freezing front. The extent of freezing-induced water redistribution depends on the balance between heat flow and water flow. If the delivery of latent heat (the product of the water flow rate and the latent heat of fusion) to the freezing front matches the (sensible) heat flow rate away from it, the downward movement of the freezing front will stall as ice accumulates, filling available pore space. Under proper circumstances, ice can continue to form even after all pore space is filled, resulting in the formation of lenses of pure ice and displacement of the soil above, a process known as frost heave.^[1]

RELATIONSHIPS

Once ice nucleation has occurred in a freezing soil, the pressure in the liquid phase is related to the temperature through the Clapeyron equation:

$$\frac{p_w - \pi}{\rho_w} - \frac{p_i}{\rho_i} = L_f \frac{T - T_0}{T_0}$$

where p_i and p_w are the gauge pressures within the ice and water phases, ρ_i and ρ_w are the densities of the respective

phases, and π is the osmotic pressure of the soil solution. L_f is the latent heat of fusion (334 kJ/kg), T is the temperature, and T_0 is the temperature at which bulk water freezes, both in K.

Because water also exists as a vapor, the relationship between phase pressures and temperature can also be expressed psychrometrically:

$$\frac{p_w - \pi}{\rho_w} - \frac{p_i}{\rho_i} = \frac{RT}{M} \ln \frac{e_i(T)}{e_w(T)}$$

The saturation vapor pressures over ice and water, e_i and e_w , are tabled functions of temperature, while R is the gas constant (8.314 J/mol/K) and M is the partial molar mass of water (0.018 kg/mol). Evaluation of either equation shows that the quantity on the left side has a temperature dependence of approximately 1.2 kJ/kg/K. The osmotic pressure depends on the solute concentration of the soil water, but in any event, its temperature dependence is quite small, on the order of π/T . In many cases, and particularly in unsaturated soil, the gauge pressure within the ice phase, p_i , should be negligible. Hence the change in p_w (more commonly known as matric potential) with respect to T in a freezing soil will be about 1.2 MPa/K. The relationship between the temperature of a frozen soil and its liquid water content is graphically expressed in a freezing characteristic curve, analogous to the moisture characteristic curve that describes water retention in unfrozen soil.^[2,3]

APPLICATIONS

Can this information be used to estimate the liquid water content of a frozen soil? Yes, but with some important restrictions and caveats.^[2] It has been shown that the moisture characteristic and the freezing characteristic are

superimposable for porous media that are completely colloidal, i.e., clay suspensions, where surface tension effects are negligible. For such materials, the liquid water content corresponding to a specific pore water pressure (matric potential) should be the same whether the cause of the gauge pressure is drying or freezing (ignoring the issue of hysteresis). For media that are devoid of colloids, i.e., pure sands and silts, the rules for similarity are also clear, but different. Here, the ratio of the surface tensions of an air–water interface (σ_{aw}) and an ice–water interface (σ_{iw}) must be taken into account. For such materials, it has been experimentally shown for a given soil that for similar water contents during drying and freezing the pore water pressure will be more negative in the drying soil by a factor of 2.2, the ratio of σ_{aw} to σ_{iw} . In other words, at a specific pore water pressure, there will be less liquid water in the frozen soil than in the drying soil. Unfortunately, most soils contain both colloidal and noncolloidal particles, so *a priori* scaling of a freezing characteristic curve from known moisture characteristic data is not possible. Developments in instrumentation and methodology offer means to directly measure soil freezing characteristic curves.^[3,4]

Internal water movement within a frozen soil is a difficult process to study. Because thermodynamic similarity exists between freezing and drying, i.e., both are functions of pore size, it is expected that for similar liquid water contents, the hydraulic conductivity of a frozen soil and an unfrozen soil will also be similar, but experimental verification data are scant. Coarse-textured sandy soils, when unfrozen, generally have high saturated hydraulic conductivities but because their pores drain at gauge pressures close to zero, their conductivities dramatically decrease with desaturation. For the reasons mentioned above, the decline in liquid water content (as a function of p_w) upon freezing is even steeper, so such soils rapidly lose their ability to conduct water as they freeze. Finer textured soils generally have lower saturated hydraulic conductivities but because the decrease in water content upon freezing is more gradual, their conductivities decrease more slowly, so that they can often sustain more water movement in the frozen state than sandy soils. For this reason, they are more prone to frost heave. Frost heave can cause tremendous structural damage to buildings and roadways and can also harm plants and trees.

Despite the substantial decrease in water potential accompanying freezing, often there is minimal movement of water as the freezing front penetrates. Unless there is a ready supply of water close to the plane of freezing, the soil beneath will soon become desiccated, causing a sharp decrease in hydraulic conductivity, to the point that the delivery of latent heat cannot match the rate of sensible heat loss, so the freezing front moves downward. Thus initially dry soils may freeze with little or no redistribution of moisture. Consistent with the

Clapeyron equation, the largest water-filled pores freeze first, at temperatures closest to 0°C, and as the temperature decreases, the water in progressively smaller pores freezes. Even in relatively moist soils, the hydraulic conductivity is often insufficient to support anything more than local redistribution of moisture. This is manifested in ice crystal formation in large pores and cracks, without significant change in profile water distribution at a scale detectable by traditional methods of soil moisture measurement.

The infiltration of water into frozen soil has received considerable attention, due to the catastrophic flooding that can occur sometimes following snowmelt or rainfall on frozen soil. It is commonly accepted that freezing dramatically lowers the infiltration capacity of a soil. This is generally true, for reasons alluded to earlier. In wet soils, particularly those with water tables near the surface, water movement during freezing fills large pores and in extreme cases creates lenses of pure ice. Also, just as the largest water-filled pores are the first to freeze, they are also the last to melt, at temperatures closest to 0°C. These are the pores that are most important in infiltration; consequently, infiltration rates are much lower if they are ice filled. Even in well-drained unsaturated soils, local redistribution during freezing is often sufficient to fill large pores at the soil surface with ice, retarding subsequent infiltration. However, in drier soils, particularly if they freeze rapidly, the large pores can remain air filled, and infiltration rates may approach those measured under unfrozen conditions.^[5] Although initial infiltration rates into frozen soil are usually quite low, often resulting in ponding, there have been observations of abrupt increases in infiltration prior to the complete disappearance of frozen soil below.^[6,7] A number of possible explanations have been suggested but none have been experimentally demonstrated.

CONCLUSION

Heat and water relations in frozen soil are difficult to study. Researchers are hampered by the inability to separately measure water and ice contents at similar spatial scales and by the complications arising from simultaneous, coupled transport of heat and water in a deformable medium. Formal theory describing phase equilibrium in ideal, uniform porous medium is well established, but application of that theory to transient phenomena in structured, yet plastic, soils with complex mineralogy is elusive.

Fungi

Serita Frey

School of Natural Resources, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Soil fungi are a highly diverse group of microscopic, eukaryotic organisms. They are indeterminate organisms, growing and extending indefinitely as long as sufficient resources are available to sustain their growth. The mycelial growth form is well suited to the heterogeneous soil environment where nutrient resources are spatially separated over long distances at the microbial scale. Fungi are heterotrophs, obtaining carbon, nutrients, and energy through the extracellular degradation and absorption of organic matter from their external environment. Oxygen is generally required for growth. Fungi are an integral part of the soil biotic community.

INTRODUCTION

Soil fungi are a highly diverse group of microscopic, eukaryotic organisms belonging to the Kingdom Fungi (Mycota). While some are single-celled fungi (e.g., yeast), most are multicellular with a mycelial morphology comprising a network of tube-like strands (hyphae). They are indeterminate organisms, growing and extending indefinitely as long as sufficient resources are available to sustain their growth.^[1] The mycelial growth form is well suited to the heterogeneous soil environment where nutrient resources are spatially separated over long distances at the microbial scale. Fungi are heterotrophs, obtaining carbon, nutrients, and energy through the extracellular degradation and absorption of organic matter from their external environment. Oxygen is generally required for growth. Fungi are an integral part of the soil biotic community, significantly contributing to the decomposition of organic matter, the release and turnover of nutrients, the formation and maintenance of soil structure, the extension of plant root systems via the formation of mycorrhizal networks, and the promotion and suppression of plant disease.^[2]

FUNGAL CLASSIFICATION

Fungi obtained kingdom status in 1969 when Whittaker^[3] proposed a five-kingdom classification system that recognized the following five distinct organism groups: Plantae, Animalia, Fungi, Monera (bacteria and cyanobacteria), and Protocista (algae, slime molds, and protozoa). This classification scheme has been much debated, largely due to advances in molecular biology which allow the direct analysis of genetic material (i.e., RNA and DNA). These molecular analyses have greatly enhanced biologists' ability to discern evolutionary relationships and have provided extraordinary insight into the wealth of biological diversity

present on earth. Several new classification schemes containing a greater number of kingdoms have been proposed to adequately represent this diversity.^[4,5] Fungi are assigned to the following four subdivisions within Kingdom Fungi: Basidiomycotina, Ascomycotina, Zygomycotina, and Mastigomycotina.^[6]

Classification within these groups is based on the characteristics of both vegetative and reproductive structures. The oomycetes, an important group of organisms that include several highly destructive plant pathogens (e.g., *Pythium* and *Phytophthora* species), were traditionally classified as fungi within the Mastigomycotina, but are now generally considered to represent a separate evolutionary line from the "true fungi" and are placed with the brown algae in the Kingdom Chromista.^[7]

GROWTH AND REPRODUCTION

Fungi—often incorrectly labeled as plants—superficially resemble plants in that they possess cell walls, are generally non-motile, and reproduce by microscopic, seed-like structures (i.e., spores). However, fungi differ from plants in several key features, including being heterotrophic and having cell walls composed mainly of chitin rather than cellulose. Heterotrophy results in fungi obtaining nutrients and energy by producing and releasing extracellular enzymes which break complex organic compounds down into simpler constituents (e.g., sugars and amino acids) that are then absorbed back through the fungal cell wall and plasmalemma. Molecular evidence suggests that fungi are, in fact, more closely related to animals than to plants.^[7,8]

The vegetative structure of most fungi consists of a filamentous network of hyphae that extends outward by growing at the hyphal tips. Interconnected hyphae are collectively referred to as the fungal mycelium or thallus. Hyphae may be branched or unbranched and may or may

not contain septa, the rigid but porous cross-walls that provide structural support and regulate the flow of cytoplasm. Fungi reproduce either sexually or asexually by producing microscopic propagules called spores.^[2] Spores may be produced singly or in visible fruiting bodies (e.g., mushrooms). In addition to serving as dispersal agents, spores also provide an important survival mechanism, often resistant to low temperatures, low nutrient availability, desiccation, ultraviolet (UV) irradiation, and other adverse environmental conditions.^[2,6] Dormant spores may remain viable for long periods of time, germinating when conditions again become favorable for vegetative growth.^[2]

ABUNDANCE AND DIVERSITY

Fungi, with bacteria, comprise the majority of the total living biomass of soil biota.^[9,10] In some soils, fungal biomass equals or exceeds that of plant root biomass.^[11] The hyphae of filamentous fungi are usually 2 to 10 μm in diameter, but can reach extensive lengths and cover large areas. A gram of soil typically contains several hundred meters of fungal hyphae and may easily contain several hundred different fungal species. Despite their microscopic size, a single fungal mycelium can cover an area of several hectares.^[12,13] Approximately, 70,000 fungal species have been described worldwide, but an estimated 1.5 million species exist, indicating that 95% of all extant species have yet to be identified.^[14] Limitations to the adequate characterization of fungal diversity include the methodological constraints historically associated with the identification of microscopic organisms, the lack of trained fungal taxonomists, and the economic cost associated with the large research efforts required for this type of work.^[15]

FUNGI AND ECOSYSTEM FUNCTION

Soil fungi can be grouped into three general functional groups (Table 1). While plant pathogenic fungi, such as *Fusarium* and *Rhizoctonia*, cause significant losses of agricultural crops each year, most soil fungi are beneficial and perform a number of critically important ecological

functions. A primary role of fungi in any soil is the decomposition of plant residues. Saprophytic fungi produce a suite of extracellular enzymes capable of depolymerizing plant cell constituents such as cellulose, hemicellulose, and lignin. During the decomposition process, fungi immobilize (i.e., retain in their biomass in organic form) and mineralize (i.e., release to the environment in inorganic form) nutrients simultaneously, with the balance between these two processes determining the plant availability of nutrients such as nitrogen, phosphorus, potassium, and sulfur. In addition to nutrient immobilization, fungi are known to potentially accumulate toxic substances within the mycelium, including radionuclides and heavy metals.^[9] The branching of fungal hyphae around soil particles, combined with the production of extracellular polysaccharides that serve as binding agents, promotes the formation of stable soil aggregates.^[15] This fungal-mediated process modifies air and water relations by altering soil permeability and may be an important mechanism for the physical protection of soil organic matter.^[16] Many saprophytic fungi promote the suppression of plant disease, either by producing antibiotics inhibitory to disease-causing organisms or by out-competing pathogens for available resources,^[11] e.g., the fungus *Chaetomium globosum* produces an antibiotic suppressive to *Fusarium*, the agent of seedling blight on maize.^[11]

Mutualistic associations involving fungi include lichens, endophytes, and mycorrhizas. In all cases, a fungus establishes a mutually beneficial relationship with an autotrophic organism. Lichens are fungus–alga or fungus–cyanobacterium associations in which the alga or cyanobacterium partner captures energy through photosynthesis, and the fungal partner provides structural support, supplies mineral nutrients, and helps regulate water relations.^[11] Endophytic fungi grow within living plants, obtaining nutrients from the plant without causing noticeable damage and, in at least some cases, providing protection from insects and plant pathogens;^[2] e.g., some grasses (e.g., ryegrass) can be infected with a fungus that produces toxins thought to inhibit insect attack.^[2]

Mycorrhizal fungi, which form an intimate association with plant roots, enhance the uptake and transfer of mineral nutrients to the plant host in exchange for carbon. “Indeed, mycorrhizas, not roots, are the chief organs of nutrient uptake by land plants.”^[17] Phosphorus is often the nutrient of primary importance, but nitrogen, zinc, and sulfur have also been shown to be absorbed and transported by mycorrhizal fungi.^[11] Some mycorrhizal species participate in water as well as nutrient absorption and may also provide protection against root pathogens.^[11] Mycorrhizas are currently grouped into seven types, namely arbuscular mycorrhizas, ectomycorrhizas, ectendomycorrhizas, arbutoid mycorrhizas, monotropoid mycorrhizas, ericoid mycorrhizas, and orchid mycorrhizas.^[17] Arbuscular mycorrhizas are the most common and are formed by fungi in the order Glomales (Zygomycetes) in association with roots of a

Table 1 Functional groups of soil fungi.

Group	Function
Saprotrophs	Decomposition of organic matter
	Nutrient immobilization and release
	Accumulation of toxic materials
	Aggregate formation and stabilization
	Suppression of pathogens
Mutualists	Transport of nutrients and water to plant roots
	Protection from root pathogens and heavy metals
Pathogens	Cause plant and animal disease

wide range of plants.^[17] Fossil evidence suggests that mycorrhizal-like structures, resembling modern arbuscular mycorrhizas formed by fungi in the genus *Glomus*, were present 460 million years ago and may have played an important role in the successful establishment of early terrestrial plants.^[18,19] Ecological studies indicate that mycorrhizal species diversity in soil can influence the diversity and productivity of plant communities.^[20]

Fungi are sensitive to disturbance, and human-induced modifications of the soil environment often have negative impacts on the soil fungal community. Tillage of agricultural land disrupts the establishment and development of hyphal networks, thereby significantly reducing fungal hyphal lengths and biomass within the plow layer.^[21,22] Increased nitrogen inputs, through fertilization^[23,24] and atmospheric deposition,^[25] have been implicated in the decline of both fungal biomass and fungal species diversity. Exposure to UV-B radiation, which has been increasing due to thinning of the protective stratospheric ozone layer, has been shown to influence fungal growth and the relative competitive abilities of different fungal species.^[26] Reductions in fungal biomass, activity, and diversity could have significant implications for the functioning of terrestrial ecosystems.

Abstract

Human population, resource consumption, and waste generation have increased rapidly throughout the Anthropocene. Feeding this growing population, supplying needed resources, and dealing with waste products require expanding our knowledge of and the sustainable use of soil resources. At the same time, anthropogenic activity has created major changes in ecosystems, including the soil system. These changes may alter the functions of soils that mankind depends on to sustain both life and modern standards of living. To ensure productivity, conservation, and general respect of soils, humans need to overcome the stigma of “dirt” or “filth” often associated with soil and instead treat soil as a vital natural resource. Doing so will require expanded use of modern technologies/advances including proximal and remote sensing, geographic information systems, and spatial statistics. However, it is equally important to recognize that the models and predictions generated by these new techniques are limited by the quality and quantity of field-based observations. Therefore, more traditional field investigations, including soil landform studies, continue to be important to soil science heading into the future.

INTRODUCTION

Studies indicate that during the Anthropocene, humanity has experienced exponential growth of consumption, generation of waste, and population. The human economy depends on the planet’s natural capital that provides all ecological services and natural resources, and since about 1980, human demands have exceeded the capacity of the earth to sustain such use.

Cultural attitudes determine the role of soils in the world as our fragmented global community struggles to resolve the global issues of food security, environmental protection, and overall sustainability. A variety of world views influence the search for a sustainable, socially acceptable balance among soil functions that provide for viable economic growth and development, safe healthy environments, and intergenerational equity.

Linking entire social systems in a web of production, distribution, and consumption, agriculture often fore-shadows the degree of economic well-being. Because

agriculture operates simultaneously in the realms of ecology and economics, each of which marks time by different clocks, decisions affecting food security and environmental protection have become increasingly complex and variable over time and space.

THE PEDOSPHERE

Soils are a critical interface between society and natural resources. Thus, the basic principles of the organization and functioning of the earth’s soil cover, the pedosphere, can provide a scientific basis for addressing global environmental, social, economic, agronomic, and human health issues throughout the 21st century.^[1]

Natural soils result from the interaction of processes taking place over time on the earth’s surface. Most involve gases and liquids that transform the solid phase of the surficial materials into features recognized as soils. These processes are influenced by soil-forming factors—namely,

climate, biota, topography, parent material, and time—leading to great heterogeneity in the world's soil cover. Geomorphic processes that alter the landscape by erosion, transport, and deposition of rocks and sediments and the interaction of biological systems with soils are all subject to major modifications associated with global and regional climate changes. The result is an intricate patchwork of soils, ranging in size from a few square meters to thousands of square kilometers.

For millennia, naturally evolving soils were dominant in the world, and determining the properties and distributions of major kinds of soils and their local geographic associates enabled societies to effectively tap these resources to satisfy their needs. Soils provided habitats for plants, animals, and microorganisms. Soils possessed the capacity for fertility and potential productivity because of water, physical support, and biological interactions that provided nutrients.^[2]

Mapping the pedosphere and deciphering the sequence of events and processes causing such complexity have revealed a multidimensional hierarchy that is meaningful for assessing many kinds of soils and predicting soil-related behavior.

ALTERED ECOSYSTEMS

For more than a century, scientific studies of soils as natural independent entities on the earth's surface have contributed to a better understanding of the interconnectivity of the earth's systems.^[3] As societies introduced more and more invasive procedures, they drastically altered ecosystem processes and biogeochemical cycles. Although some ecosystems have been enhanced, more have been degraded and are being used unsustainably.^[4,5] It has become relevant to monitor, predict, and mediate the behavior and responses of both natural and artificial (anthropogenic) soil environments and landscapes. It is believed that many changes being made in ecosystems are increasing the likelihood of detrimental, nonlinear changes.^[6]

With increases in the size of the human population and its increasing rate of consumption, the available natural resources are stressed, some beyond their limits of resilience.^[1] One estimate is that human resource use in 2000 was about 20% above the global carrying capacity.^[7] When soils are so stressed, they are unable to return to their former productive states without massive external inputs. Thus, sustainable reconciliation of societal desires and natural resource capabilities is commonly jeopardized.

FUNCTIONS OF SOILS

Functions of soils commonly include: 1) promoting biomass transformations; 2) serving as the earth's geomembrane to filter and buffer; 3) providing biological habitats; 4) providing usable materials; and 5) serving as sources and repositories of our cultures.^[8]

Soils are primarily used by most people for the production of food, feed, fuel, and fiber. The capacity to store and release water and the ability to renew, store, and release plant nutrients have dominated agronomic and forestry research and practical experimentation for many years, going back as far as the 16th century. Biomass transformations are highly dependent on the microbiological populations that inhabit soils and facilitate the formation and use of beneficial compounds.

The pedosphere is a sensitive geomembrane which mediates the transfer of air, water, and energy into, out of, and among the biosphere, atmosphere, hydrosphere, and lithosphere (Fig. 1). Temperatures are moderated with depth, and water and associated compounds are filtered, retained, stored, and transferred in ways that contribute to clean, healthy environments.

Soils are the habitat for millions of organisms, ranging from cellular bacteria to burrowing animals. Communities of microorganisms decompose organic materials, facilitate the release of mineral elements, and produce the chemical and biological compounds essential for life on earth.^[2]

Many soils are directly used as raw materials for constructing dams and foundations; others are source materials for landscaping industrial and urban sites; and some are ingredients for bricks, aluminum, ceramic products, and medications. Most transportation networks and urban communities rest on soils. In addition, soils are excavated to create disposal sites for society's numerous wastes. Soils that are disturbed or removed from their natural environments are commonly called "dirt." As such, displaced soil materials are generally considered a nuisance in our daily activities and need to be washed out, removed, and personal contact with them minimized. Historically, stigma was often attached to those associated with the "filth and dirt" of using and managing soils.^[9]

Fig. 1 The pedosphere results from the interaction throughout space and time of the atmosphere, biosphere, and hydrosphere with the lithosphere. Once developed, the pedosphere plays a significant role in supporting and maintaining life on the planet.

In the stories of most indigenous cultures, the earth is sanctified and revered as a vital element of nature, thereby reinforcing humankind's link with it. This sacredness remains in the use of soils as cemeteries and as places where the spirits of ancestors reside. Archeological investigations often involve deciphering the memories of times and events recorded in soil properties.^[10]

CONTINUING NEEDS

It is obvious that soils continue to be used to maintain and improve productivity for food, feed, fuel, and fiber for a long time because the supply of elements and minerals necessary for life is derived, directly or indirectly, from soils. Healthy ecosystems and environments depend on soil-hosted microorganisms that facilitate filtering and purifying. There is much to be learned about how soils behave in maintaining healthy anthropogenic landscapes. Unprecedented demands to safely handle wastes and provide major increases in food and feed are enormous challenges.^[7,11]

Perhaps less appreciated is the need of the human psyche for renewal through contact with nature. It appears that psychological well-being is, in part, related to our communion with the beauty, tranquility, and mysterious forces of nature.^[12] Although we are connected to the land and soils in ways that most of us do not readily comprehend, we do recognize the sense of belonging and the feeling of renewal associated with our contacts with the natural world. Is it a "dust thou art, and to dust thou shall return" syndrome in which our life cycle is subsumed in other natural life cycles? Whatever the explanation, the human-to-nature relationship is important, and soil is vital to our survival and growth.

CHANGING DEMOGRAPHICS

It is estimated that during the 21st century, more people will be living in cities than currently live on earth.^[13] As cities evolve into megacities through the use of adjacent lands, the unique culture of urban dwellers, including their estrangement from rural landscapes and ecosystems, also develops.^[1]

Ecological functions of soils are common in extensive rural areas of the earth, where the productive capacity of soils is easily recognized. In urban landscapes, which are very different in appearance, structure, and composition, the role of soils is commonly not observed, or even imagined, except in parks and residential lawns and gardens. Sewers and trash trucks remove numerous waste products, smoke stacks and vehicles exude particulates into the atmosphere, and streams and rivers wash away other debris. In rural landscapes, many of these functions are provided by the pedosphere—the covering of soils that seems to be ubiquitous and so common that it is taken for granted.

How much relatively undisturbed land would be required to provide the energy and products consumed in

an urban environment, and to adequately handle its wastes? Such a measure could be thought of as a city's environmental footprint.^[11] We do not measure and monitor the enormous fluxes that occur in urban environments, yet they are becoming major stressors on our global habitat.

INFLUENCING THE ROLE

Is there a possibility of simply stretching ecological theory to encompass urban ecosystems? It can be argued that our understanding of dynamics and processes of populations and soils can be extended to homeowners' associations and pavement.^[11] If people act as other organisms do, guided by individual self-interest, there is no basis for a moral or aesthetic call to environmental stewardship. Is there, perhaps, a spiritual or moral dimension that defies explanations offered by evolution or natural selection?

The challenge of understanding urban ecosystems requires specialists from many different disciplines but it also requires that at least some individuals think in interdisciplinary and transdisciplinary ways—a task that may be difficult to accomplish.

The single most important force of landscape change in urban areas is land conversion driven by institutional decisions, population growth, and economic forces.^[11] A city's footprint, which indicates the dependence of an urban ecosystem on other ecosystems, may be tens or hundreds of times larger than the city itself.

Soil ecosystems are being altered, and even created, to meet the expectations of urban communities. Consequently, the kinds and patterns of adjacent soil landscapes are important to the monitoring and assessment of environmental health and sustainability.^[4,7]

THE FUTURE

There are many challenges that need to utilize soil knowledge if they are to be adequately addressed. A global consensus must develop that will clearly define a minimum set of common norms and international standards for sustainable uses of various kinds of soils. Knowledge about the limitations of specific kinds of soils for particular uses is essential for informed decisions and agricultural policies (Table 1). For every conceivable use of soil, there is a hypothetical ideal soil with the right set of properties and supporting processes to achieve a satisfactory level of success. Comparing local soils with a specified "ideal" soil can lead to recommended measures that minimize limitations and contribute toward attaining the expected behavior of such an ideal soil. When local economics of managing individual soils are considered, it is possible to develop rankings of suitability and economic feasibility.

Since the 1980s, the amount of field work done in soil science has significantly declined due to shifts in priorities leading to cuts in funding and diminished field training at

Table 1 Soil attributes that can become constraints to achieving desired balances of soil functions if excessive demands are placed on soil resources

Soil attribute	Constraint
Resilience	Recovery from disturbance
Productivity	Capability for plant growth and yield
Responsiveness	Capacity for external enhancement
Sustainability	Dynamic equilibrium of interactions
Resistance	Stability to maintain current condition
Flexibility	Multiplicity of uses related to properties
Pedoclimate	Location and extent of suitable climate
Residence time	Capacity to store and release compounds
Geography	Availability due to location or intricacy of pattern

colleges and universities. New techniques utilizing proximal and remotely sensed information gathered with geographic positioning system technologies and analyzed in geographic information systems, often incorporating geostatistical models, have grown in popularity.^[14] This popularity is due in part to the high data density that proximal and remote sensing can provide and quantitative models linking these measurements to specific soil properties. The popularity is also partly because proximal and remote sensing techniques are less expensive than traditional field work. Providing soil information that can address the challenges of the future will require the high data density that proximal and remote sensing can provide evaluated with geostatistical and other advanced mathematical techniques. However, it is very important that field work continues to be supported as well.^[14] The models and predictions generated from proximal and remote sensing techniques are limited by the quality and quantity of field-based observations and measurements of soil and landscape parameters. Therefore, more traditional field investigations, including soil land-form studies, need to be supported so that information modeled from proximal and remotely sensed data can be verified as being meaningful or improved when field checks show the model to be flawed. The soil scientist of the future will need to be able to combine competence in the field with competence in quantitative methods.

CONCLUSIONS

Humanity surpassed the earth's capacity to support our ever-increasing demands on natural resources several decades ago. There is great disparity among nations in their ecological footprints, thus the challenges of implementing practices to attain sustainability are many. Supplying quantitative soils information at scales suitable to address needs is a challenge facing the soil science community. Soils are vital to supplying food, feed, fiber, and fuel to support the development of future generations; consequently, improved understanding of

the functions and limitations of local soils is relevant to helping meet the desires for resources and the handling of wastes in a sustainable global habitat for all humanity.

Gas and Vapor Phase Transport

Dennis E. Rolston

Land, Air, and Water Resources, University of California—Davis, Davis, California, U.S.A.

Abstract

Diffusion is the principal mechanism in the interchange of gases between the soil and the atmosphere. Fick's law of diffusion can describe the diffusion of gases in soils as long as the restrictive conditions for the applicability of the equation apply. The soil-gas diffusion coefficient, D_p , is the fundamental property that must be known to use Fick's law to calculate gas transport in soils. Values of D_p change with soil-air content and tortuosity. Techniques for accurately measuring D_p in soil cores are well established. However, because measured data for D_p are often not available, equations to predict D_p from easily obtainable soil-physical parameters have been developed. It is well established that different equations are needed to estimate D_p for undisturbed and for disturbed soil samples. Equations for undisturbed soil must include parameters that take into account the effects of soil type, such as texture, structure, and pore-size distribution, on D_p . Soil-type effects on D_p in sieved and repacked soils appear to be minor.

INTRODUCTION

Diffusion is the principal mechanism in the interchange of gases between the soil and the atmosphere. The interchange results from concentration gradients established within soil by respiration of microorganisms and plant roots; by production of gases associated with biological reactions such as fermentation and nitrogen transformations; and by soil incorporation of materials such as fumigants, anhydrous ammonia, pesticides, and various volatile organic chemicals in toxic waste sites. The diffusion of water vapor within the soil also occurs due to differences in vapor pressure gradients induced by temperature differences or by evaporative conditions at the soil surface.

TRANSPORT PHYSICS AND EQUATIONS

The diffusion velocities of gas mixtures in porous media are related to each other in a complex manner dependent on the mole fraction of each gas, the molar fluxes of each gas, and the binary diffusion coefficient of each gas pair. If gravity effects are ignored or diffusion occurs only horizontally, the well-known Stefan–Maxwell equations provide the theoretical framework for diffusion of gases in soils. Fick's law for diffusion is a restrictive case of the Stefan–Maxwell equations and is generally applicable for only a few special cases.^[1] One of these cases is for the diffusion of a trace gas in a binary mixture, meaning that the mole fraction of the tracer gas is small. The second special case is for diffusion of two gases in a closed system (total pressure remains constant). In this case, neither gas needs to be in trace amounts. A third case where Fick's law is applicable is for a three-component system where one of the gases

exists in trace amounts and the binary diffusion coefficients of the other two pairs do not differ much from one another (basically the first case). Examples of this case would be for the gas pairs of nitrogen (N_2)–oxygen and N_2 –argon.

Assuming that the special case conditions are met, Fick's law is given by as follows:

$$\frac{M_g}{At} = f_g = -D_p \frac{dC_g}{dx} \quad (1)$$

where M_g is the amount of gas diffusing (g gas), A is the cross-sectional area of the soil (m^2 soil), t is time (sec), f_g is the gas flux density (g gas/ m^2 soil/sec), C_g is concentration in the gaseous phase (g gas/ m^3 soil air), x is distance (m soil), and D_p is the soil-gas diffusion coefficient (m^3 soil air/m soil/sec).

MEASUREMENT OF THE SOIL-GAS DIFFUSION COEFFICIENT

The soil-gas diffusion coefficient, D_p , is the fundamental property that must be known to use Eq. 1 to calculate gas transport in soils. Values of D_p change with soil-air content and tortuosity (crookedness of the diffusion path).

The standard laboratory method for measuring the soil-gas diffusion coefficient is based on establishing gas concentration, C_o , within a chamber (Fig. 1). One end of a soil core of concentration C_s is placed in contact with the gas within the chamber.^[2] The other end of the soil core is maintained at concentration C_s . The gas of interest diffuses either into or out of the chamber depending upon the concentration C_o compared to that outside the core. Obviously, the other gases making up the atmosphere will diffuse in an opposite direction to that of the gas of interest. The time

Fig. 1 Schematic diagram of the apparatus design used for measuring the soil-gas diffusion coefficient of a soil core.

rate of change of concentration in the chamber is related to the soil-gas diffusion coefficient and can be described by equations for unsteady diffusion of gas. Several investigators^[2] have used similar procedures.

The unsteady diffusion of a gas, which is non-reactive (physically, biologically, and chemically), is described by the combination of Fick's first law (Eq. 1) and the continuity equation (conservation of mass)

$$\epsilon \frac{\partial C_g}{\partial t} = D_p \frac{\partial^2 C_g}{\partial x^2} \quad (2)$$

where ϵ is the soil-air content ($\text{m}^3 \text{ air}/\text{m}^3 \text{ soil}$).

In developing Eq. 2, it is assumed that the soil is uniform with respect to the diffusion coefficient and that ϵ is constant in space and time. A simple solution of Eq. 2 that allows for the determination of D_p from laboratory measurements is available.^[2,3]

PREDICTIVE EQUATIONS FOR THE SOIL-GAS DIFFUSION COEFFICIENT

Gas transport and fate simulation studies often depend on accurately estimating gas diffusivity (D_p/D_0) as a function of soil-air content (ϵ) from easily obtainable physical parameters of the soil because measured data of $D_p(\epsilon)$ are often not available. Many empirical models for predicting the gas diffusivity have been proposed, such as the well-known Millington–Quirk equation,^[4] with varying degrees of prediction accuracy.^[5] A series of papers^[5–9] have offered new equations that appear to greatly increase the predictive accuracy. Separate equations are needed for undisturbed

soils compared to sieved and repacked soils. To accurately predict diffusivity in undisturbed soils, the effects of texture and structure on the diffusivity must be considered.

Undisturbed Soil

It has been shown that the Campbell^[10] pore-size distribution (water retention) parameter, b , is an effective parameter to describe effects of soil type (soil texture and structure) on $D_p(\epsilon)$ in undisturbed soils^[5–8] to give

$$\frac{D_p}{D_0} = \Phi^2 \left(\frac{\epsilon}{\Phi} \right)^{2+3/b} \quad (3)$$

where D_0 is the gas diffusion coefficient in air (without soil; $\text{m}^2 \text{ air}/\text{sec}$), Φ is soil total porosity ($\text{m}^3 \text{ voids}/\text{m}^3 \text{ soil}$), and b is the Campbell pore-size distribution parameter, corresponding to the slope of a plot of the log of the soil-water pressure potential vs. the log of the volumetric soil-water content.

It has also been shown that there is a significant effect of macroporosity on D_p .^[8] In this respect, macroporosity is defined as the air-filled porosity at a soil-water pressure head of $-100 \text{ cm H}_2\text{O}$ (-10 kPa), corresponding to the volumetric content of soil pores with an equivalent pore diameter larger than $30 \mu\text{m}$. The macroporosity (ϵ_{100}) is found by subtracting the volumetric soil-water content measured at a soil-water pressure head of -100 cm from the soil total porosity. Using this concept results in an additional equation as follows:

$$\frac{D_p}{D_0} = (2\epsilon_{100}^3 + 0.04\epsilon_{100}) \left(\frac{\epsilon}{\epsilon_{100}} \right)^{2+3/b} \quad (4)$$

To summarize, Eq. 4 appears slightly more accurate and is recommended if both ϵ_{100} and b are known, whereas Eq. 3 is recommended if only b is known.

If the Campbell pore-size distribution parameter, b , is not measured, clay fraction is a good indicator of b ^[11,12] and is given by as follows:

$$b = 13.6 \text{ CF} + 3.5 \quad (5)$$

Thus, Eq. 5 can be used to determine b to be subsequently used in either Eq. 3 or 4.

Sieved and Repacked Soil

Soil-type effects, such as texture and structure (manifested through pore-size distribution), on gas diffusivity in sieved and repacked soils appear to be minor and can likely be neglected.^[9,13,14] A simple, physically based model^[9] for $D_p(\epsilon)/D_0$ in sieved and repacked soils is given by as follows:

$$D_p/D_0 = \epsilon^{1.5} \left(\frac{\epsilon}{\Phi} \right) \quad (6)$$

The reduction term (ϵ/Φ) describes the increased tortuosity in a wet soil, compared to a dry soil at the same soil-air content, because of interconnected water films. This equation has been shown to give accurate predictions of the soil-gas diffusion coefficient in sieved and repacked soil samples.^[9]

CONCLUSION

Although techniques for accurately measuring D_p in soil cores are well established, measured data for D_p are often not available and predictive equations are required. It is well established that equations needed to estimate D_p for undisturbed and for disturbed soil samples are indeed different. Equations for undisturbed soil must include soil-physical parameters that take into account the effects of soil type, such as texture, structure, and pore-size distribution, on D_p . Soil-type effects on D_p in sieved and repacked soils appear to be minor.

Gelisols

James G. Bockheim

University of Wisconsin, Madison, Wisconsin, U.S.A.

Abstract

Gelisols occur in the polar and in some alpine regions and are soils containing permafrost within 100 cm of the soil surface or gelic materials within 100 cm and permafrost within 200 cm of the surface. Gelisols originate from cryopedogenic processes that include cryoturbation, freezing and thawing, cryogenic sorting, ice segregation, and cryodesiccation. The low temperatures in Gelisols give rise to cryostatic pressure development and migration of water with resultant ice buildup. Therefore, Gelisols are differentiated from other soils primarily on the basis of thermal characteristics and physical properties that are readily observed in the field. The three main types of Gelisols are Histels (organic soils with permafrost), Turbels (mineral soils with cryoturbation), and Orthels (other mineral soils with permafrost in the upper 100 cm). The pedon concept is especially important for sampling Gelisols and is determined by the size of the repeating units of patterned ground features, e.g., <2, 2–7, or >7.

INTRODUCTION

Gelisols, the permafrost-affected soils, comprise 13.8 million km² or about 10% of earth's land surface. They occur primarily in the Arctic (83%) and high-mountain regions (17%) (Fig. 1). Because only 0.36% of Antarctica is ice-free, it contains 0.1% of the world Gelisols. Gelisols are of global concern because they contain many protected areas, support indigenous people who depend on the land and surrounding oceans for sustenance, may be subject to considerable impacts from human development (oil, coal, gas, and gas hydrate exploitation), and are already experiencing global warming. Gelisols have been used in relative dating of soils, correlation of glacial deposits, understanding glacier dynamics, and as extraterrestrial analogs.^[1]

Gelisols have permafrost within 100 cm of the soil surface or gelic materials within 100 cm of the surface and permafrost within 200 cm of the surface.^[2] Permafrost is a thermal condition in which a material remains below 0°C for two or more years in succession; it may be ice-cemented or, in the case of insufficient interstitial water, dry. The zone above permafrost that is subject to seasonal thawing is known as the active layer. A transition layer reflecting long-term changes in the active layer often separates the active layer and the underlying permafrost. Gelic materials are defined as seasonally or perennially frozen mineral, or organic soil materials that show cryoturbation (frost churning), ice segregation, or cracking from cryodesiccation.

THE PEDON AS A BASIC SOIL UNIT FOR GELISOLS

The pedon is the basic soil unit for sampling in *Soil Taxonomy*^[2] and is especially important for describing,

classifying, and sampling Gelisols, which often occur in areas with patterned ground. Patterned ground is a general term for any ground surface that is ordered into polygons, nets, circles, or stripes as a result of freezing and thawing processes. Fig. 2 shows mudboils in Antarctica resulting from such processes. Each mudboil is 1–1.5 m across. The pedon is defined so as to encompass the full cycle of patterned ground with a 2-m linear interval or a half cycle with a 2–7-m cycle. This interval is suitable for most patterned ground features. In the case of large-scale (>7 m) patterned ground, such as ice-rich low-center polygons on the North Slope of Alaska, two pedons are established—one within the center of the polygon and the other within the ice wedge. Therefore, each mudboil in the figure represents a single pedon for descriptive and sampling purposes.

CLASSIFICATION OF GELISOLS

There are three suborders within the Gelisol order—Histels, Turbels, and Orthels; they are distinguished on the basis of

Fig. 1 Distribution of Gelisols in the Northern Hemisphere. **Source:** Natural Resources Conservation Service.

Fig. 2 Mudboils on Nelson Island in the South Shetland Group of Antarctica. Each mudboil is 1–1.5 m across.

organic matter content, and for mineral soils, whether or not there is evidence for cryoturbation.^[2]

Histels have 80% or more organic materials by volume within the upper 50 cm or to a restricting layer. They are subdivided into five great groups based on the nature of the underlying material and the degree of decomposition—Glacistels, Folistels, Fibristels, Hemistels, and Sapristels.^[2]

The Fibristel illustrated in Fig. 3 contains organic soil materials extending into permafrost at 90 cm. Disturbance to the surface-insulating layer may cause ice layers, such as ice wedges, to thaw and the soil to collapse, a condition known as thermokarst (Fig. 4). The key properties of Histels are abundant organic materials ranging from woody to highly amorphous materials, a high moisture-holding capacity, and a pH, that for an array of Histels, may range from as low as 2.5 to above 7.0. Histels comprise 9% of the Gelisols globally, especially in North America and Russia.

Turbels represent a second suborder of the Gelisols; they are mineral soils subject to cryoturbation. Turbels comprise about 56% of the Gelisols on a global basis. Cryoturbation is evidenced by irregular or broken horizons, involutions, organic matter accumulated on the surface of the permafrost, oriented rock fragments, and silt coatings and silt-enriched subsoil horizons that result from freezing and thawing, frost heaving, and cryogenic

Fig. 3 A Fibristel in northern Alaska. The organic soil materials extend from the surface into the permafrost at 90 cm.

Fig. 4 A landform in Northern Canada containing ice-wedge polygons that have thawed following disturbance of the surface organic materials, resulting in a condition known as thermokarst.

sorting. Cryoturbation is caused primarily by differential frost heave, but its action can be enhanced by cryostatic pressure, differential swelling, and load casting on poorly drained sites.

Fig. 5 shows a Haploturbel in Northern Canada. This pedon shows intense cryoturbation. Although the underlying concept of Turbels is that they are subject to cryoturbation, they may contain diagnostic horizons that are common to soils not having permafrost. However, these horizons are recognized at the great group level. There are seven great groups within the Turbels (Histoturbels, Aquiturbels, Anhyturbels, Molliturbels, Umbrturbels, Psammiturbels, and Haploturbels) that link them with other soils not containing permafrost.^[2]

It should be emphasized that cryopedogenic processes such as cryoturbation, thermal cracking, and ice segregation are soil-forming processes characteristic of soils with

Fig. 5 A Haploturbel in Northern Canada. This pedon showing intense cryoturbation.

Source: From C. Tarnocai.

Fig. 6 A Spodic Psammoturbel in northern Russia. The soil is excessively drained, developed in sandy floodplain deposits, and contains weakly developed and cryoturbated spodic materials in the upper part. Permafrost occurs at 140 cm.

permafrost. They should not be viewed as operating against the other soil-forming processes in low-latitude soils; rather, they are distinctive processes producing horizons and properties that are uncommon to other soil orders. Processes common to the other soil orders operate in Gelisols but at a lesser magnitude because of the dominance of cryopedogenic processes.

The third suborder within the Gelisols is the Orthels, which are other mineral soils containing permafrost within the upper 100 cm. These soils comprise 35% of the Gelisols globally. The Orthels are subdivided into eight great groups (Historthels, Aquorthels, Anhyorthels, Mollorthels, Umbrorthels, Argiorthels, Psammorthels, and Haplorthels) that more or less are parallel to those in the Turbels and that link them to soils not containing permafrost. Fig. 6 shows a Spodic Psammoturbel in northern Russia. The soil is derived from sandy floodplain deposits and contains weakly developed spodic materials.

GELISOLS AND LAND USE

Gelisols offer special challenges to land management for interpretation and practices, including construction (structures and pipelines), mining, forestry, and agriculture. For

Fig. 7 An apartment complex in the Chersky in the Russian Far East that is built on stilts to avoid heat transfer, melting of permafrost, and subsidence.

example, structures must be built on refrigerated pilings or aboveground (Fig. 7) so that heat from the structure does not melt the permafrost and cause subsidence. A main concern with Gelisols is that they are large carbon (C) sinks. The concern is that warming in the arctic could increase the thickness of the seasonal thaw layer and enhance heterotrophic respiration, releasing additional carbon dioxide to the atmosphere. In this case, Gelisols would become a C source. In contrast, warming in Antarctica, especially along the Antarctic Peninsula, is causing recession of glaciers and increases in land area and plant cover, in which case Gelisols would become a C sink.

Abstract

An option that has been proposed to combat the buildup of greenhouse gases in the atmosphere is the capture of carbon dioxide (CO₂) at large stationary sources, such as power plants, and injection into a geologic formation for permanent storage—generally referred to as carbon capture and storage. This entry provides an overview of the major geologic targets in sedimentary basins for long-term storage of CO₂. These targets are oil and gas reservoirs, deep coal beds, and deep saline formations saturated with brackish water or brine.

INTRODUCTION

Atmospheric levels of carbon dioxide (CO₂) have risen significantly from preindustrial levels of 280 parts per million (ppm) to present levels of 384 ppm.^[1] Evidence suggests that the observed rise in atmospheric CO₂ levels is the result of expanded use of fossil fuels for energy. The predictions of increased global energy use indicate a continued increase in carbon emissions^[2] and rising concentrations of CO₂ in the atmosphere unless major changes are made in the way we produce and use energy—in particular, how we manage carbon.^[3,4] One approach to managing carbon is to use energy more efficiently to reduce our reliance on the major carbon emissions source—fossil fuel combustion. Another option is to increase the use of low-carbon and carbon-free fuels and technologies (nuclear power and renewable sources, such as solar energy, wind power, and biomass fuels). The third strategy is to manage carbon through geologic storage (GS), sometimes referred to as geologic sequestration. GS is part of the process of carbon capture and storage (CCS), which involves separation and capture of CO₂ at the point of emission followed by injection and storage in a deep underground geologic formation (Fig. 1).^[5]

CO₂ sinks are a natural part of the carbon cycle; however, due to the concerns about global climate change related to greenhouse gas emissions, efforts are underway to better utilize CO₂ sinks as a form of carbon management to offset emissions derived from fossil fuel combustion and other human activities. The concept of carbon sinks has become more widely known because the Kyoto Protocol^[6] under the United Nations Framework Convention on Climate Change^[7] allows the use of engineered CO₂ sinks as a form of carbon offset. Natural sinks include the oceans, plants and other photosynthetic organisms, and geologic formations.

In 2006, about 28 billion metric tons of CO₂ was emitted globally into the atmosphere, in that the United States' share being about 5.6 billion metric tons.^[8] About half of this came from large stationary sources, primarily coal-fired power plants, which produce flue gases with a low CO₂ concentration (<20%).

GS of CO₂ to limit atmospheric emissions has been underway for more than a decade with projects that have provided significant data and experience, such as Sleipner in Norway,^[9] In Salah in Algeria,^[10] and a joint U.S.–Canadian effort at the Dakota Gasification facility and Weyburn field.^[11] Numerous field projects in saline

Fig. 1 The illustration of CCS process showing major pathways for geologic and terrestrial storage.

Source: National Energy Technology Laboratory, U.S. Department of Energy.^[5]

formations, oil reservoirs, and coal seams are being developed in the United States and Canada through the U.S. Department of Energy's Regional Carbon Sequestration Partnerships initiative.^[12]

It is expected that large numbers of new power plants and processing facilities based on coal and other nonliquid hydrocarbons (i.e., coal-to-liquid fuels and coal-to-synthetic natural gas plants) will be built in the coming decades, in both the developing world and some areas of the developed world. These new facilities have the potential for being appropriately fitted, during design and construction, with efficient CCS technologies.^[5] Existing plants can be retrofitted for CO₂ capture. If we are to effectively manage the CO₂ emissions from all these plants, the use of geologic carbon sinks will be required.

GS is most efficient at depths greater than 2600 feet (800 m) because CO₂ increases in density and becomes a supercritical fluid at pressures that naturally exist at such depths (Fig. 2). Supercritical fluids take up much less volume and diffuse better through the pore spaces in storage formations than gases or ordinary liquids.

GS TARGETS

GS requires a reservoir and seal (caprock) to trap CO₂ for long periods of time. GS can take place in the following three major geologic targets in sedimentary basins^[13]: deep saline formations, saturated with brackish water or brine; oil and gas reservoirs; and deep coal beds (Fig. 1).

Basalt formations and organic-rich shales have been proposed as potential GS options, but their utility and suitability need to be demonstrated.^[5,14] Keeping the CO₂ in the subsurface requires geologic conditions that create a trap consisting of one or more layers of impermeable rock (caprocks), which are layers of sediments (shale or evaporates) that impede CO₂ movement and act to trap the CO₂ for millennia.

Saline Formations

Saline formations are layers of porous rock, such as sandstone and limestone, which are saturated with brine. They are much more extensive than coal seams or oil- and

Fig. 2 CO₂ injected at depths below 2600 feet (800 m) increases in density with depth and becomes a supercritical fluid. Supercritical fluids take up much less space and diffuse better than either gases or ordinary liquids through the tiny pore spaces in storage rocks. The blue numbers show the volume of CO₂ at each depth compared to a volume of 100 at the surface.

Source: Data from CO₂CRC (<http://www.co2crc.com.au/imagelibrary/>).

gas-bearing reservoirs and represent an enormous potential for CO₂ storage. However, much less is known about saline formations because of a lack of characterization data, such as that acquired through resource recovery from oil and gas reservoirs and coal seams. Therefore, there is greater uncertainty regarding the volume and suitability of saline formations for CO₂ storage.^[14]

The suitability of deep saline formations for the storage of CO₂ is the result of various physical and chemical mechanisms that act on different timescales, such as dissolution and mineral precipitation. In stratigraphic and structural traps, CO₂ storage capacity can be estimated by following procedures similar to those for oil and gas reservoirs but still involves an understanding of temperature, pressure, and salinity constraints.

In the large areas that do not have well-defined traps, a general rough estimate of capacity can be achieved through time-discounted estimates of dissolution potential. With time, increasingly secure physical and chemical trapping mechanisms come into play, and the overall security of storage in saline formations increases (Fig. 3). However, it is critical to understand the displacement and migration of saline water and the injected CO₂ within these deep formations. The GS potential of saline formations is very large, but accurate capacity estimates require significant local refinement and modeling. The GS potential for saline

formations in portions of the United States has been estimated to range from 900 billion metric tons to more than 3300 billion metric tons.^[5]

Fig. 3 As time passes, increasingly secure trapping mechanisms come into play, and overall storage security increases. This is especially important in saline formations where relatively well-understood structural and stratigraphic trapping operates over short time frames.

Source: Data from CO₂CRC (<http://www.co2crc.com.au/imagelibrary/>).

Oil and Gas Reservoirs

Mature oil and gas reservoirs have held crude oil and natural gas over millions of years. They consist of a layer of permeable rock with a layer of non-permeable rock (cap-rock) above, such that the non-permeable layer forms a trap that holds the hydrocarbons in place. Oil and gas fields have many characteristics that make them excellent target locations for GS of CO₂. The geologic conditions that trap oil and gas are also the conditions that are conducive to CO₂ storage.

As a value-added benefit, CO₂ injected into a mature oil reservoir can enable incremental oil recovery. A small amount of CO₂ will dissolve in the oil, increasing the bulk volume and decreasing the viscosity, thereby facilitating flow to the wellbore. Typically, primary oil recovery and secondary recovery via water flooding produce 30–40% of a reservoir's original oil in place (OOIP). A CO₂ flood allows the recovery of an additional 10–15% of the OOIP. Oil and gas reservoirs are the best understood of the potential GS options as a result of exploration for, and production of, hydrocarbons. The volume of CO₂ that can be stored in an oil and gas reservoir can be estimated based primarily on the reservoir's depth and size and the volume of produced fluids.^[14]

Enhanced oil recovery (EOR) using CO₂ flooding has proven to be valuable technology in areas with natural CO₂ supplies, as miscible and immiscible CO₂ flooding can revitalize mature oil fields. Limited availability of CO₂ in most regions constrains production from CO₂-based EOR. However, carbon capture applied to advanced electric power generation facilities and other industrial processes could produce large quantities of CO₂, which could be sold to oil and gas producers for use in enhanced oil and gas recovery while at the same time storing CO₂ in reservoirs deep beneath the earth's surface. An initial estimate of GS potential of oil and gas fields in the United State exceeds 83 billion metric tons.^[5]

Coal Seams

Unminable coal seams are seams that are too deep or too thin to be economically mined. All coals have varying amounts of methane adsorbed onto pore surfaces, and wells can be drilled into unminable coal beds to recover this coal bed methane (CBM). Initial CBM recovery methods, such as dewatering and depressurization, leave a considerable amount of methane in the formation. Additional recovery can be achieved by sweeping the coal bed with CO₂. Depending on coal rank and properties, two or more molecules of CO₂ are adsorbed for each molecule of methane released, thereby providing an excellent storage site for CO₂ with the additional benefit of enhanced coal bed methane (ECBM) recovery. Similar to maturing oil reservoirs, unminable coal beds are good value-added candidates for CO₂ storage.

The suitability of a coal seam for CO₂ GS can be evaluated on technical, economic, and regulatory (resource protection) criteria.^[14,15] However, limited operating experience with ECBM technology and poor understanding of CO₂/coal interactions under reservoir conditions have limited storage applications. A number of pilot projects in coal seams are underway or planned to address gaps in knowledge. An initial estimate of GS potential of coal seams in the United State is 150–180 billion metric tons.^[5]

MONITORING, VERIFICATION, AND ACCOUNTING (MVA)

GS of CO₂ requires MVA activities at the storage site, as well as risk assessment and development of mitigation strategies that can be implemented should a problem arise. Effective application of MVA technologies ensures the safety of sequestration projects, with respect to both human health and the environment, and provides the basis for establishing carbon credits on trading markets for sequestered CO₂. Monitoring methods, such as subsurface pressure monitoring, geochemical monitoring, well logging, and surface monitoring, will help demonstrate that the CO₂ is contained in the storage formation and not leaking. Other techniques, such as seismic imaging and electromagnetic imaging, provide an indication of where the CO₂ plume might migrate in the formation so that the monitoring strategies can be modified during the project's life. Risk assessment focuses on identifying and quantifying potential risks to humans and the environment associated with geologic CO₂ storage and helps

Fig. 4 GS will be a long-term process stretching over decades of active operations and possibly hundreds of years of custodial care. GS of CO₂ will include developing an understanding of storage sites and long-term CO₂ behavior in the subsurface, implementing monitoring and verification techniques, maintaining regulatory oversight, establishing long-term custody of the stored CO₂, and keeping the public informed.

to ensure that these risks remain low. For well-selected, designed, and managed GS sites, risks are estimated to be comparable to those associated with existing hydrocarbon activities.^[13]

CONCLUSION

GS is one of the several strategies for reducing CO₂ emissions to the atmosphere. Several projects injecting CO₂ into geologic formations have been underway for more than a decade, and more than 30 years of industrial experience has demonstrated that CO₂ can be safely transported and injected into the deep subsurface. There are a number of challenges to the widespread implementation of the GS of CO₂, including reducing capital and operating costs, improving understanding of long-term CO₂ behavior in the subsurface, improving monitoring methods, developing a satisfactory regulatory environment, establishing long-term custody of the stored CO₂, and keeping the public informed and accepting of the technology (Fig. 4). Numerous pilot and large-scale field projects are underway or planned throughout the United States^[12] and the world^[13] over the next few years. Information from these projects should go a long way toward facilitating the development of geologic CO₂ storage.

Geology and Soil

Kenneth R. Olson

Department of Natural Resources and Environmental Sciences, University of Illinois at Urbana-Champaign, Urbana, Illinois, U.S.A.

Abstract

Geology is the study of earth, its internal structure, its materials, its chemical and physical processes, and its physical and biological history. One of the most important geological discoveries was that rocks could form by crystallization of molten material. Rocks do change from one kind to another. As rocks get exposed to the surface weather, particles move downstream, eventually to be deposited as sediments that lithify into sedimentary rocks. By tracing distributions of rock materials, early geologists were able to link sediments to highly consolidated, mineralogically distinct metamorphic rocks.

ATMOSPHERE, HYDROSPHERE, AND LITHOSPHERE

The crust, mantle, and core account for 99.97% of the mass of the earth.^[1] The lithosphere includes the earth's crust and upper mantle. The term has previously been used to describe the entire portion of the earth that is composed of rocks. The remaining 0.03% comprises the atmosphere and the hydrosphere. The hydrosphere includes the portion of the earth's surface that is covered by water. The hydrosphere behaves as an intermediate reservoir for carbonates, silicates, and other mineral groups leached from the rock of the continents and carried to the oceans by rivers.^[1] Both silicates and calcium carbonate follow involved paths from the time they are weathered from continental rock, until they are deposited on the sea floor.

The composition of the atmosphere is strongly influenced by the cycling of water from the oceans to the continents and by its return to the oceans in rivers and subsurface flow. The amount of free oxygen in the atmosphere seems to remain essentially constant. Volcanic gases contain only traces of molecular oxygen but eject large quantities of molecular hydrogen, carbon monoxide, and sulfur dioxide. These gases react with atmospheric oxygen to produce carbon dioxide, water vapor, and sulfur dioxide. The lithosphere, which consumes free oxygen through weathering of rock, and the biosphere, which produces oxygen through photosynthesis, maintain this equilibrium. The control over this equilibrium may be a feedback mechanism involving the organisms whose by-products and remains become constituents of sedimentary rock.

CYCLING OF ELEMENTS

Oxygen, silicon, aluminum, and iron contribute 96% by volume of the elemental composition of the earth's crust.^[2]

The other elements only occupy the remaining 4%. Individual atoms or molecules of such elements such as carbon, nitrogen, oxygen, and sodium change form countless times as they cycle through the atmosphere, biosphere, and lithosphere.^[1] Oxygen, for instance, may be converted from a neutral atom to dissolved gas, from combined molecule to ionized particle, to protoplasmic components, and, perhaps, back to the ionic state as a constituent of rock.^[1] Other atoms, such as sodium or silicon, may be more constrained in the variety of chemical forms they may assume. These and other representative routes are indicated in a revised and modified scheme shown in [Fig. 1](#).

CHEMICAL WEATHERING PROCESSES

"Weathering" is a collective term for the combined effects of all the physical and chemical processes that break down and transform pre-existing rock materials near the earth's surface to products that are more stable under the physical and chemical conditions at the surface. Weathering constitutes the response of rock materials to several forms of energy as a function of time.^[1] The products of weathering include solids (i.e., sediments and soils) and liquids (including the solutions of salts present in rivers and the ocean). Each physical and chemical factor of weathering affects the outcome of the weathering process. These factors and related variables of the rock cycle, including erosion, transportation, and sedimentation, combine to operate as a complex chemical sorting system which distributes products of different composition to various sites of deposition.

Soils are the result of leaching, oxidation, and dissolution of surface materials by the percolation of groundwater and by humic acids derived from oxidized organic materials. New minerals, such as clays, are formed by the chemical alteration of the original mineral of the bedrock.^[1]

Fig. 1 Cycling of elements.

Source: From Jackson.^[1]

The chemical weathering process develops a soil profile ranging from heavily weathered surface materials down to unaltered rock. The soil zone is the zone of transition between solid rock and the atmosphere. The solid rock, or bedrock, usually has numerous tiny cracks or joints. Chemical weathering caused by water, which fills the cracks, attacks the joints' surfaces and enlarges the cracks.

PARENT MATERIAL

Parent material is the initial or starting material from which a soil develops. This initial material can include either consolidated rock or unconsolidated material deposited by gravity, wind, or water and consists of specific minerals of different sizes, or even plant materials of various plant types.^[2] Mineral matter inherited from rocks is referred to as soil parent material because it is the principal ingredient from which soils are formed.^[3] However, the principal parent materials of organic soils are decomposing plants.

In many cases, relief prior to and during soil formation is related to the nature of the initial soil material. In broad river deltas, crests of natural levees near the stream channels have more coarse material than the areas beyond the levees that are nearly level and have the finer textured

initial material.^[4] In steeper topography, where the valleys below the mountain ranges are characterized by broad alluvial-colluvial fans, the initial material near the mountain range contains more coarse and angular material than areas farther away from the mountain range.^[5]

After unconsolidated parent material is deposited on a stable landscape, or after bedrock has been exposed at the earth's surface, soil formation begins and continues over time. The rate of soil formation depends on the climate, including temperature and rainfall. It also depends on vegetation and the activity of other organisms, which live on or in the parent material. These organisms help convert parent materials to soil.

Russian pedologists^[6] identified parent material as one of the five significant soil-forming factors. Early approaches to soil survey and classification were based on the geology and composition of the soil-forming material.^[7,8] The geologic origin and composition of the initial material were identified by the terms "Agranite soils" or "Aglacial soils." Soils that originate from a parent material inherit the mineral types found in them. Over time, these original minerals are weathered (dissolved) and new minerals form and accumulate in the soils.^[2]

Russian soil scientists^[9] showed the controlling effects of parent material on soil properties. Jenny^[10] conducted a systematic analysis of the relationship between soil properties and parent materials from which the soils developed. Jenny proposed parent materials as an independent soil-forming factor, defining parent material as "the state of the soil system at time zero of soil formation." The physical body of soil and its associated mineralogical and chemical properties are the starting point for the interaction of other soil-forming factors. Previous weathered rock—even a previous soil—could be considered as parent material.

The properties of modern soil are the result of the composition of the surficial layer, which existed when the other factors started to impact, and the alterations resulting from the effect of these factors over time. Properties of younger soils are greatly influenced by parent material. Weathering and pedogenic processes result in characteristics of the original parent material being eliminated. Extremely resistant initial material, such as quartz or sand, may still exist in old, weathered soils. It can be difficult to separate the nature (or characteristics) of the initial material and its influence on soil, the kind of "preweathering" of the initial material before becoming parent material for the soil, and the effects of the other soil-forming factors on the parent material of this soil. The complex environmental history (climatic and vegetation changes in the geologic past) makes it difficult to separate parent material influences on soil properties from other factor effects.

Rock types influence the soil properties of the modern soil. The impact of rock type on soil properties was organized by Buol, Hole, and Mc Craken^[11] into the following subdivisions: sedimentary, igneous, and combinations of mineralogically similar metamorphic and igneous rocks.

Sedimentary rocks include unconsolidated glacial deposits, loessial deposits, unconsolidated coastal plain sediments, and consolidated rock, such as limestone and dolomites, sandstones, and shales.

Siliceous crystalline rocks include more “acidic” quartzose, igneous, and metamorphic rocks including granites, granite gneiss, and schists. Dark-colored ferromagnesian rocks include andosites, diorites, basalt, and hornblende gneiss. Volcanic ash parent materials are composed of non-crystalline materials, any glass fragments, bits of the easily weatherable feldspars, ferromagnesian minerals, and varying amounts of quartz.

Mineral components of many soils are inherited almost exclusively from parent materials, while others are developed mostly *in situ* during the course of weathering and pedogenesis. Primary minerals are formed at high temperature in igneous and metamorphic rocks. Secondary minerals are formed at lower temperature in sedimentary rocks and soils.^[12]

CONCLUSION

The basic model of soil implies that soils are dynamic and geographical. In soil systems, the processes or driving forces are best described as dynamic rather than static. Morphological properties of soil are the result of processes acting on parent materials. In addressing the influence of parent materials in soil genesis, Chesworth^[13,14] stated that “time has the result of modifying the parent material effects so that only in young or relatively immature soils will the parent material exert its strongest influence on the soil-forming process. That influence will be an inverse function of time.”

Geomorphology

Robin N. Thwaites

*School of Natural Resource Sciences, Queensland University of Technology,
Brisbane, Queensland, Australia*

Abstract

The principles, concepts, and models of soil geomorphology are most effectively applied in surveys and mapping of soil landscapes. Many types and methods of survey have been, employed, but modern technology and computer modeling have advanced the application of soil geomorphological principles and techniques. There are many other applications of soil geomorphological techniques—primarily, research into landscape evolution and climate change, quaternary studies, landscape ecology and paleoecology, archaeology, paleontology, environmental engineering, and mineral exploration. Technology for remote sensing of the land surface and soil materials has also aided soil geomorphological investigation, particularly the use of airborne and satellite environmental sensors, as well as ground-based sensing. The greatest impact of all techniques in soil geomorphology, however, has been that of computer spatial modeling, particularly the use of digital terrain models as land surface analogies for analyzing the dynamics and effects of hillslope and drainage basin processes.

INTRODUCTION

The soil, the landscape in which it forms, the materials from which it forms, and the processes that form it all constitute the 3-D systems through time that are part of the science of geomorphology. Soil geomorphology (or pedogeomorphology) is the study of the evolution (temporal aspects) and distribution (spatial aspects) of soil and soil materials and the landscapes in which they are formed and altered.^[1] It is a science that relies strongly on geological and geomorphological principles and techniques.^[2] These have unique application to soil that augments the science of pedology to express the concepts of soil landscapes and soil landscape systems. As such, soil geomorphology provides: 1) principles for the understanding of the soil landscape and 2) a process by which models of soil material variation and distribution at all scales can be derived. It is an assessment of the genetic relationships between soils and landforms and the resulting landscapes.^[3]

SOIL GEOMORPHOLOGICAL CONCEPTS

The roots of the soil geomorphological approach can be traced to the more applied aspects of soil science in the 20th century from the need for mapping soil distribution. Thus, there is the fundamental concept of the soil catena from Milne^[4,5] and the procedure of Integrated Survey in Australia in the 1940s and 1950s to produce land systems^[6] that express the application of what are now termed soil geomorphological principles and the concepts laid out by

Ruhe^[7–9] in the United States and by Butler,^[10] among others, in Australia. From this basis, the more theoretical and specific expressions of soil geomorphology have been developed by Conacher and Dalrymple,^[11] who coined the term pedogeomorphology from their work in New Zealand and Australia; Birkeland,^[12,13] Daniels,^[2,14] and others in the United States; Gerrard^[3] and Huggett^[15] in the United Kingdom; Dan Yaalon in the arid lands; and Paton^[16] and Pain and Ollier^[17] among others in Australia. The incorporation of geological and geomorphological principles^[18,19] into pedology allows the investigation and better understanding of soil materials and processes at different spatial and temporal scales as well as understanding soil as earth materials in the geological landscape.

Geomorphic and pedological processes act together on the hillslope, which can be viewed as the fundamental 2-D unit of study. This is the basis of the catena concept and the expression of the “toposequence” that arises from referral to the state factor model of soil formation.^[20] Later, soil geomorphic studies also focused on temporal development, investigating “chronosequences” for pedogenetic and landscape evolution, which, again, had developed as a function of the state factor model. However, from a more spatial geomorphological viewpoint, hillslope processes together form a *soil geomorphological system* from which the fundamental 3-D unit, a soil landscape unit,^[15] is derived. One of the important principles of soil geomorphology is the development and expression of the concepts of “soil landscapes” and “soil landscape systems.”^[15,17]

The physical focus of soil science, through its basis of soil–plant interactions and land use management, has

Fig. 1 Milne's original catena on a uniform parent material (granite): (1) shallow skeletal dark gray loam, (2) deeper red earth, (3) coarse granite grit in ferruginous cement, (4) washed sand, (5) silty sand, (6) clayey sand, and (7) clay floor.

Source: From Redrawn from Milne.^[4]

traditionally been more on the solum (the A and B soil horizons) rather than on the whole regolith (the solum plus the C/D soil horizons, saprolite, and other non-bedrock materials), though there have been exceptions to this, largely concerning the nature and influence of parent material, particularly with glacial materials in the mid-United States. Therefore, another major principle for soil geomorphology is to include the nature and dynamics of the regolith and geologic materials in models of soil evolution and distribution as part of soil landscape systems.

SOIL GEOMORPHOLOGICAL MODELS

The fundamental basis for models of soil geomorphology is that of surface and subsurface hillslope processes as an open system. The original model in this respect is the

catena, expressed by Milne^[4,5] and expanded to other environmental scenarios by Gerrard,^[3,21] whereby natural surface processes operating over distance along hillslopes are invoked to explain characteristic pattern of soil material variation (Fig. 1).

This coupled with the acknowledgment of the influences of topography and parent material over time from the state factor model^[20] of pedogenesis [itself a reemphasis of Dokuchaev's (1883) pedological model], and the explicit relationships between geomorphology and pedogenesis made by Wooldridge^[22] laid the foundation for the soil geomorphological conceptual models of the 1950s and 1960s. The revision of the pedogenetic paradigm by Simonson^[23] to introduce the concept of it as an open, dynamic system of accessions, removals, transfers, and transformations then provided the basis for the 3-D soil geomorphological system models that are accepted. The introduction of geomorphological principles and the

Fig. 2 The 3-D, dynamic soil landscape system as a primary soil geomorphological model. Catenary sequences in multiple directions follow surface and subsurface water flow lines within a drainage basin landform.

Source: Adapted from Huggett.^[15]

hydrological processes operating within the hillslope system over varying depths of time were the tenets of the first real soil geomorphological models: by Ruhe^[8,9] in the United States, by Butler^[10] as cycles of stability and instability on the hillslope in Australia, then by Dalrymple, Blong, and Conacher^[24] as the dynamic, process-based “9-unit land surface” model as the basis for *pedogeomorphic* (soil geomorphological) research.^[11] They believe that there are four main aspects to soil geomorphological research that distinguishes it from either pedology or geomorphology: the conceptualization, the classification, the modeling, and the explanation of soil–slope relationships at all scales.

More functional and mechanistic 3-D soil geomorphic system models were developed in the 1970s and 1980s, the most outstanding of which is that presented by Huggett^[15] of the soil landscape system (Fig. 2), which expresses meso- and macroscale dynamics of soil materials and water over drainage basins and treats natural erosion and deposition as variable but continuing processes over time and space. The advent of more powerful computer modeling facilities has allowed for complex process simulation and analysis of these system models through digital terrain models (DTMs) as mathematical representations of the land surface.

CONCLUSION

The principles, concepts, and models of soil geomorphology are most effectively applied in surveys and mapping of soil landscapes. Many types and methods of survey have been employed, but modern technology and computer modeling have advanced the application of soil geomorphological principles and techniques. There are many other applications of soil geomorphological techniques: primarily, research into landscape evolution and climate change, quaternary studies, landscape ecology and paleoecology, archaeology, paleontology, environmental engineering, and mineral exploration. Many of these techniques are outlined by Daniels and Hammer^[2] and Gerrard,^[3] such as soil stratigraphical interpretation, tephrochronology in volcanic regions, radioisotope dating of materials and relative dating of land surfaces, and the use of environmental and paleoenvironmental indicators. Technology for remote sensing of the land surface and soil materials has also aided soil geomorphological investigation, particularly the use of airborne and satellite environmental sensors [e.g., airborne gamma ray spectrometry (or “radiometrics”), airborne electromagnetic (EM) induction, geomagnetism, and satellite multichannel infrared and hyperspectral sensors] as well as ground-based

sensing (e.g., ground penetrating radar, EM sensors, and radio spectrometry). The greatest impact of all techniques in soil geomorphology, however, has been that of computer spatial modeling, particularly the use of DTM as land surface analogies for analyzing the dynamics and effects of hillslope and drainage basin processes. Such advances are outlined and discussed well by Lane, Richards, and Chandler^[25] and Wilson and Gallant.^[26] This has allowed much complex theoretical and functional modeling of soil landscape processes (via the geomorphic effects of topography) over space and time to aid the task of soil landscape survey and mapping as well as soil geomorphic process simulation and prediction for environmental problem solving.

Abstract

Near-surface geophysical methods have become an important tool for agriculture. Geophysical investigations for agriculture are most often focused on the first 2 meters directly beneath the ground surface, which includes the crop root zone and all, or at least most of the soil profile. Resistivity, electromagnetic induction, and ground-penetrating radar are the three geophysical methods most commonly employed for agricultural soil investigations; however, optical reflectance and γ -ray spectroscopy are increasingly becoming more widely utilized. Temporal and spatial variation of conditions and properties in the soil profile are important considerations when conducting a geophysical survey within an agricultural setting. Geophysical methods have been applied to soil surveys, precision farming, soil water content measurement, and soil salinity monitoring; with new agricultural geophysics applications continuing to evolve. Future development of multi-sensor platforms and the use of unmanned aerial vehicles will dramatically improve geophysical soil investigation capabilities with respect to field accessibility and data interpretation.

INTRODUCTION

Agricultural geophysics as described in this entry involves the application of physical quantity measurement techniques to provide information on conditions or features within the soil environment. With the exception of borehole geophysical methods and soil probes with electrical conductivity, optical, and penetration resistance sensors, these techniques are generally non-invasive with physical quantities determined from measurements made mostly on or

directly above the ground. Agricultural geophysics tends to be heavily focused on a 2 m zone directly beneath the ground surface, which includes the crop root zone and all, or at least most, of the soil profile.^[1] Complexities encountered with agricultural geophysics include transient soil temperature and moisture conditions, which can appreciably alter, over a period of days or even hours, the values of measured soil physical quantities (especially electrical conductivity and dielectric constant (K)). Additionally, physical quantities measured in the soil environment with

geophysical methods often exhibit substantial variability over very short horizontal and vertical distances. The three geophysical methods most commonly used for agricultural purposes are resistivity, electromagnetic induction (EMI), and ground-penetrating radar (GPR). However, optical reflectance and gamma (γ)-ray spectroscopy are gaining more widespread utilization. All five of these employed agricultural geophysics methods are summarized in the next section of this entry.

GEOPHYSICAL METHODS

Resistivity

The resistivity method, employed in its most conventional form, uses an external power source to supply electrical current between two “current” electrodes inserted at the ground surface. The propagation of current in the subsurface is three-dimensional, and so too is the associated electric field. Information on the electric field is obtained by measuring the voltage between a second pair of “potential” electrodes also inserted at the ground surface. The two current and two potential electrodes together comprise a single four-electrode array. The magnitude of the current applied and the measured voltage are then used in conjunction with data on electrode spacing and arrangement to determine an apparent soil electrical conductivity (EC_a), for a bulk volume of soil. The current and potential electrodes are often arranged inline, and the depth of investigation increases with increased length of the electrode array.

Continuous measurement galvanic contact resistivity systems integrated with global positioning system (GPS) receivers have been developed in the United States and Europe specifically for farm field soil investigations (Fig. 1). These resistivity systems can have more than one four-electrode array providing shallow investigation depths of 0.3–2 m, with short time or distance intervals between the continuously collected discrete EC_a measurements. The location for each EC_a measurement is determined accurately by GPS. For the system shown in Fig. 1, steel coulters (disks) that cut through the soil

Fig. 2 EMI DUALEM-21 S GCM (DUALEM, Milton, Ontario, Canada) measuring soil electrical conductivity at a golf course green.

surface are utilized as current and potential electrodes. Maps of EC_a spatial patterns across a farm field are generated with resistivity survey data to gain insight on lateral variations in soil properties/conditions, such as water content, soil texture, organic matter content, and so on.

Electromagnetic Induction

Electromagnetic induction (EMI) methods also measure the EC_a for a bulk volume of soil directly beneath the surface. An instrument called a ground conductivity meter (GCM) is commonly employed for relatively shallow EMI investigations (Fig. 2). In operation, an alternating electrical current is passed through one of two small electric wire coils spaced a set distance apart and housed within the GCM, which itself is positioned at, or a short distance above, the ground surface. The applied current produces an electromagnetic field around the “transmitting” coil, with a portion of the electromagnetic field extending into the subsurface. This electromagnetic field, called the primary field, induces an alternating

Fig. 1 Example of a continuous measurement galvanic contact resistivity system, Veris 3100 Soil EC Mapping System (Veris Technologies, Salina, Kansas, United States; left) and close-up of steel coulters used for current and potential electrodes by the Veris 3100 Soil EC Mapping System (right).

electrical current within the ground, in turn producing a secondary electromagnetic field. This secondary field extends back to the surface and the air above. The second wire coil acts as a receiver measuring the resultant amplitude and phase components of both the primary and secondary fields. The amplitude and phase differences between the primary and secondary fields are then used, along with the intercoil spacing, to calculate an “apparent” value of EC_a for a bulk volume of soil. Provided low induction number conditions are satisfied, the EMI depth of investigation is dependent on the spacing distance between the electric wire coils within the GCM and the orientation (vertical, horizontal, perpendicular) of the electric wire coils.^[2] As with resistivity methods, maps of EC_a spatial patterns across a farm field are generated with EMI data to gain insight on lateral variations in soil properties/conditions, such as water content, soil texture, organic matter content, etc.

Ground-Penetrating Radar

A ground-penetrating radar (GPR) system directs an electromagnetic radio energy (radar) pulse into the subsurface, followed by measurement of the elapsed time taken by the radar signal, as it travels downward from the transmitting antenna, partially reflects off subsurface boundaries or objects, and is eventually returned to the surface, where it is picked up by a receiving antenna. Reflections from different depths produce a signal trace, which is a function of radar wave amplitude vs. time. Radar waves that travel along direct and refracted paths through both air and ground from the transmitting antenna to the receiving antenna are also included as part of the signal trace. Antenna frequency, soil moisture conditions, clay content,

salinity, and the amount of iron oxide present all have a substantial influence on the distance beneath the surface to which the radar signal penetrates.^[3] The K of a material governs the velocity for the radar signal traveling through that material. Differences in K across a subsurface discontinuity feature control the amount of reflected radar energy, and hence radar wave amplitude, returning to the surface. GPS technologies are often integrated with GPR systems to obtain accurate and precise geographic positions of GPR measurements and to improve the efficiency of GPR field surveys (Fig. 3). As an end product, radar signal amplitude (energy) data are displayed as two-dimensional depth sections or aerial maps to gain insight on belowground conditions or to provide information on the positions and character of subsurface features. The GPR data collected can be used to measure soil volumetric water content (VWC), determine soil horizon depths/thicknesses, and map buried agricultural drainage pipe systems.

Optical Reflectance (UV/VIS/NIR/MIR)

Optical sensors are used to determine the soil’s ability to reflect light in different parts of the electromagnetic spectrum. The light can be from the sun or from an artificial source. Proximal optical sensors are fundamentally the same as optical remote sensors; the advantage of proximal sensors is that they can provide measurements at either the soil surface or within the soil. These proximal optical sensors can be used for on-the-spot or on-the-go soil measurements (Fig. 4). Optical sensing systems cover the ultraviolet (UV; 100–400 nm), visible (VIS; 400–700 nm), near infrared (NIR; 700–2500 nm), and mid-infrared (MIR; 2500–25,000 nm) portions of the electromagnetic spectrum. Typically, instruments used for soil measurements include their own light source (e.g., halogen light bulb or light-emitting diode). Photodiodes or array detectors are used to estimate the intensity of reflected light and relate this measure to the light reflected from a given set of standards. Both source and reflected light can be transmitted through the air, via fiber optics, or when feasible, through a contact window fabricated from highly resistive material, such as sapphire or quartz.

Measurements obtained using optical sensors can be related to a number of soil attributes, such as soil mineral composition, clay content, soil color, moisture, organic carbon, pH, and cation exchange capacity (CEC). Measurements can be viewed as direct, when relationships are based on a physical phenomenon that affects light reflectance in a specific part of the spectrum (e.g., predicting soil mineralogy or water content using characteristic water absorption bands); or indirect, when the relationships are deterministic for a finite domain and the combined effects of several soil attributes can be related to a given soil characteristic (e.g., predicting soil organic matter). Sensor calibration strategies

Fig. 3 GPR SIR 3000 system (Geophysical Survey Systems, Inc., Nashua, New Hampshire, U.S.A) integrated with Topcon HiPer XT Real Time Kinematic—GPS (RTK-GPS) receiver (Topcon Positioning Systems, Inc., Livermore, California, U.S.A).

ranged from a simple linear regression to multivariate methods, chemometrics, and data mining. Although some of these models may be applied to large geographic areas, most are linked to a specific range of soil and environments. UV radiation has also been used in combination with visible and infrared spectra to characterize iron oxides and organic matter.

γ -Ray Spectroscopy

γ rays contain a very large amount of energy and are the most penetrating radiation from natural or artificial sources. γ -ray spectrometers measure the distribution of the intensity of γ radiation versus the energy of each photon. Sensors may be either active or passive. Active γ -ray sensors use a radioactive source (e.g., ^{137}Cs) to emit photons of energy that can then be detected using a γ -ray spectrometer. Passive γ -ray sensors measure the energy of photons emitted from naturally occurring radioactive isotopes of the element from which they originate. As shown in Fig. 5, on-the-go measurement of soil elemental isotopes can be performed by installing a γ -ray sensor on a vehicle. Data interpretation may include analysis of measures related to the isotopes of potassium, thorium, and uranium, the total isotope count, or the entire energy spectrum. While shown to be a useful tool for predicting soil properties in different soil landscapes, a significant amount of preprocessing is often required to reveal relationships between the γ -ray spectra and the soil data. The γ -ray sensor signal can be

related to soil mineralogy, particle size distribution, and the effects of attenuating materials such as water and bulk density.

Inelastic neutron scattering (INS) spectroscopy relies on the detection of γ rays that are emitted following the capture and reemission of fast neutrons, as the sample is bombarded with neutrons from a pulsed neutron generator. The emitted γ rays are characteristic of the excited nuclide, and the γ -ray intensity is directly related to the elemental content of the sample. A thorough review of these methods and other proximal soil sensing methods can be found in the work of Viscarra Rossel et al.^[4]

APPLICATIONS TO SOIL SCIENCE

U.S. Department of Agriculture (USDA)/ Natural Resources Conservation Center (NRCS) Soil Surveys

Since the 1970s, GPR and EMI have been used by the National Cooperative Soil Survey (NCSS) as quality control tools to investigate, map, and interpret soils. GPR has been used principally, as shown in Fig. 6, to document the presence, depth, lateral extent, and variability of diagnostic subsurface horizons that are used to classify soils, and to name, characterize, and improve the interpretations of soil map units.^[5] GPR has also been used as a research tool to assess spatial and

Fig. 5 The Mole γ -ray sensor (The Soil Company, Groningen, Netherlands) operated by Practical Precision, Inc. (Tavistock, Ontario, Canada; left), and an energy/intensity relationship used to define reported measurements (right).

Fig. 6 Variations in the depth to shale bedrock are used to distinguish areas of shallow Weikert, moderately deep Berks and very deep Rushtown soils along this surface normalized GPR profile from the Northern Appalachian Ridges and Valley Region of central Pennsylvania.

temporal variations in soil properties. With the near completion of soil mapping in the United States, GPR is being increasingly used to support USDA conservation programs that help sustain agricultural productivity and environmental quality, address issues of soil health and soil functions, and improve the utility of soil survey data for modeling dynamic soil-hydrologic conditions and functionality at different scales.

The NCSS has used EMI to indirectly measure and map the spatial and temporal variability of soil properties at field scales. Initially used to assess soil salinity, EMI is used to map soil types; refine soil boundaries; identify contrasting soil components within soil map unit delineations; characterize soil water content and flow patterns; assess variations in soil texture, CEC, ionic composition, calcium carbonate content, organic carbon content, plant available nutrients, pH, and bulk density; and determine the depth to subsurface horizons, stratigraphic layers or bedrock, among other uses.^[6] As a tool for high-intensity soil surveys, EMI has been used to assist site-specific management, characterize

variability in soil physiochemical properties, and direct soil sampling.

Soil surveys require periodic maintenance and updating, as land use change and new demands require additional soil properties to be identified and interpreted. It is anticipated that, as soil surveys evolve, a greater understanding of the complexity and interaction of soil structures, processes, and functions will be needed at increasingly higher levels of resolution. In fulfilling this need, both EMI and GPR should find greater use in field-scaled research projects on representative soils.

Precision Farming

The agricultural production practice, called precision farming, employs spatially mapped field variables that provide assistance to producers for cropping decisions. For example, on-board computers can reference digital maps, directing automated field machinery to vary spatially the

Fig. 7 Soil EC_a and crop yield comparison for a 3 hectare field in northwest Ohio. The EC_a map (left) was obtained with a Veris 3100 Soil EC Mapping System, and values are in millisiemens/meter. The soybean yield map (right) has values in kilograms/hectare. The spatial correlation coefficient (r) between EC_a and soybean yield is -0.51 .

application rates of fertilizers, pesticides, and seeds. As precision agriculture technologies evolve, higher spatial resolution surveys of the near subsurface will be required because some soil properties, such as soil moisture and organic matter, continually change.

GPSs were a major technology trigger for precision farming during the first decade of the 21st century. GPS is a common farm tool, and it provides accurate positioning for automated field-machine guidance and speed control and supplies the real-time positioning required for the precise placement of seeds, nutrients, and pesticides, along with the geospatial mapping of harvested yields. Global positioning integrated with massive, yet inexpensive, data storage and computational power allows for large acreages to be geospatially mapped by farmers at very high resolutions.

The relatively low-sampling data density of both on-the-go resistivity and EMI instruments, when coupled with GPS positioning, supplies an effective solution for spatially mapping any soil characteristic that can be delineated by relative resistivity/conductivity boundary shifts. For these sensors, the low-data density characteristics are their greatest advantage, as this easily allows for the generation of detailed spatial field maps for very large acreages with little visual interpretation requirements. This simplicity was a trigger for their rapid adoption by farmers and farm consultants. Field maps of EC_a from resistivity or EMI surveys, often show significant correlation with crop yield maps (Fig. 7). Consequently, EC_a maps can be employed to separate the field into different management zones and thereby increase crop production.

GPR is another geophysical tool showing great promise in precision agriculture. At the small plot scale, researchers have shown GPR's abilities to spatially map numerous soil properties essential to agricultural production. Almost any near-surface soil characteristic boundary that can be spatially delineated by sharp shifts in K can be mapped. However, the extreme amount of data generated and its variability when deployed over large acreages are too time-consuming and challenging for visual interpretations. The data computational requirements and survey data storage capacity of GPR surveys were once significant limiting factors, but they are no longer. However, efficient automated processing of the GPR data sets is lacking for large watershed-scale surveys having naturally occurring soils. In contrast with other geophysical sensors having lower data quantity requirements, this geophysical technology has not gained a following by producers using precision agriculture technologies.

Unmanned aerial vehicles (UAVs) coupled with remote geophysical sensors are projected by some experts to revolutionize precision agriculture. Rapid delivery of essential, time-critical information at very low cost is the advantage of the UAV over ground-

based geophysical surveys. Aerial field surveys will become automated, inexpensive, and on-demand. For example, miniaturized and lightweight EMI sensors are being introduced for UAV surveys over large areas. The low-flying UAV will closely examine crops, pastures, and timberlands. As they should be able to detect infestations at the very outset, farmers will be able to focus precisely on containment. Cattlemen will be able to remotely monitor livestock health and pinpoint both strays and their predators while they "ride herd" overhead using UAV thermal imaging. Georeferenced nutrient and yield maps will become commonplace, advancing precision agriculture using geophysical applications even further.

Soil Water Content Measurement

GPR can be used to estimate the VWC of soil or rock, as electromagnetic velocity (v) primarily depends on the volume of water in the pore space of earthen materials. Velocity is only slightly affected by mineralogy, grain size, or temperature, so measurements of v can be converted easily to VWC. Velocity is usually converted to K before calculating VWC; several petrophysical relationships based either on empirical data or volumetric mixing models are available in the literature to convert K to VWC.^[7]

The three most common techniques for estimating VWC from GPR data are reflected waves, groundwaves, and air-launched methods.^[8] For reflected waves, the travel time to

Fig. 8 GPR groundwave data acquired over an infiltrated area surrounded by dryer soil. Wetter soils have lower velocities and longer travel times, as observed over the infiltrated zone.

a subsurface interface can be measured while the GPR antennas are pulled in the common-offset mode along a traverse. If the depth to the interface is known, the travel time is used to estimate v , which can then be related to VWC. If the depth to the interface is not known, v can be obtained by performing a variable-offset survey, which provides information on both v and depth to an interface at one location. Reflections from a continuous subsurface interface can be used to measure VWC to greater depths (i.e., the root zone) and to understand VWC variability across a field. If a continuous interface at a known depth is not available, reflections from isolated subsurface objects or buried pipes that create a reflection hyperbola in the GPR record can be used to estimate v using reflection hyperbola analysis.

GPR groundwave techniques can be used to estimate VWC by measuring the travel time of this wave. Groundwaves travel in the shallow subsurface (0 cm to ~30 cm) directly between the transmitting and receiving antennas; by noting the antenna separation and the time needed for energy to travel between antennas, v can be calculated (Fig. 8). Groundwaves do not require a reflective interface, and so can be used in many near-surface soil environments to provide continuous VWC measurements.

Air-launched GPR techniques use the magnitude of the reflection from the ground surface to estimate K . Air-launched data can be acquired and processed quickly, but have a sampling depth of less than 5 cm, and the accuracy of the data greatly diminished by vegetation, uneven soil surfaces, and vertical variations in water content, this technique can be limited in its applications.

Soil Salinity Monitoring

Soil salinity refers to the concentration of dissolved inorganic solutes in the soil solution, consisting of four major cations (Na^+ , K^+ , Mg^{2+} , and Ca^{2+}) and five major anions (Cl^- , HCO_3^- , NO_3^- , SO_4^{2-} , and CO_3^{2-}). Soil salinity reduces plant growth and, in severe cases, causes crop failure by limiting plant water uptake due to an osmotic effect making it more difficult for the plant to extract water, by specific-ion toxicity, or by upsetting the nutritional balance of plants.

In the laboratory, soil salinity is most commonly determined from the measurement of the electrical conductivity of the solution extract of a saturated soil paste (EC_e), which is proportional to the concentration of ions in the solution. However, because salinity is a highly spatially and temporally variable soil property, the use of EC_e to measure salinity at field scales is impractical due to the need for hundreds or even thousands of soil samples. The use of EC_e to measure salinity at field scales is only practical when soil sampling is directed using correlated spatial information. Geospatial measurements of EC_a using geophysical techniques (i.e., electrical resistivity, EMI, or time domain reflectometry) are sources of spatial information used to direct soil sampling to characterize field-scale soil salinity variation.

EC_a measures the conductance through not only the soil solution but also through the solid soil particles and via exchangeable cations that exist at the solid–liquid interface of clay minerals. The interpretation of EC_a measurements is not trivial due to the complexity of current flow in the bulk soil through the three conductance pathways—liquid, solid, and solid–liquid interface. Because of the three pathways of

Fig. 9 Schematic of EC_a -directed soil sampling for mapping the spatial variability of soil salinity.

conductance, the EC_a measurement is influenced by several soil properties—soil salinity, texture, water content, bulk density, and temperature. Detailed protocols for conducting an EC_a survey to characterize the spatial variability of soil salinity with EC_a -directed soil sampling are provided by Corwin and Lesch.^[9,10] A schematic of EC_a -directed soil sampling is shown in Fig. 9.

CONCLUSION

Near-surface geophysical methods have become increasingly important tools for soil investigations in agricultural settings. The methods predominantly employed are resistivity, EMI, and GPR; however, optical reflectance and γ -ray spectroscopy are beginning to find more widespread utilization. Furthermore, research indicates that other geophysical methods, such as cosmic-ray neutron probes, seismic, self-potential, magnetometry, nuclear magnetic resonance, etc., all exhibit potential for measurement of soil properties or conditions. The application to soil surveys, precision farming, soil water content measurement, and soil salinity monitoring has been described in this entry, but geophysical methods have also been used for soil investigations in forested areas, confined animal feeding facilities, and golf courses, with new applications continuing to evolve. Development of multisensor platforms and sensors mounted on UAVs will dramatically improve geophysical soil investigation capabilities with respect to field accessibility and data interpretation. Consequently, the future of near-surface geophysics in soil science appears very promising.

Geostatistics

Anja Gassner

Institute of Science and Technology, Malaysia Sabah University, Kota Kinabalu, Malaysia

Ewald Schnug

Institute for Crop and Soil Science, Julius Kuhn Institute (JKI), Braunschweig, Germany

Abstract

Scientific knowledge is based on the interaction between observations and the hypothesis that corresponds to those observations. Soil science is increasingly asked to answer questions like how do soils function in environment and how will they function and respond to a changing environment. The classical description of soil does not provide the answer. Geostatistics offers a range of tools that allow the modeling of soil functions and the interpretations of the outcome. For a range of applications such as optimal interpolation of soil properties, optimizing sampling schemes, and uncertainty analysis, to name only a few, geostatistics is essential to obtain the maximum information contained in observations and thus should be an integrated part of modern soil science.

INTRODUCTION

In the last few decades, research in soil science saw a drastic shift from an overriding importance of purely empirical examination and description of soils to a balanced approach including theory development and modeling. After the work of Jenny,^[1] soil properties are no longer seen as randomly distributed events, but rather as the outcome of an environmental process. Thus, the spatial distribution of most soil properties consists of a structural, presented by the mean or a constant trend, a spatial correlated, observations closer together are more alike than observations further apart and a random component. Geostatistics, introduced into soil science since 1980s,^[2] enables us to analyze these structures and allows us not only to predict soil classes, characteristics, and behavior, but also to assess the uncertainty of these predictions. An understanding of the spatial structure of the landscape and how it affects the correlation between soil properties is the prerequisite to develop economically feasible sampling strategies and to utilize auxiliary data to model the attribute of interest.

BASIC CONCEPTS

Theory of the Regionalized Variable

The fundamental difference between classical statistics and geostatistics is that the latter is based on the theory of regionalized variables.^[3,4] Whereas in classical statistics,

every variable is purely *random*, meaning that it has a variety of values in accordance with a particular probability distribution,^[4] in geostatistics the variable is seen as distributed in space and/or time and thus “regionalized.” So is the soil phosphorus (P) concentration [regionalized variable, $z(x)$] depending on the location $x = (x_1, x_2)^T = (\text{northing, easting})^T$. In this sense, geostatistics pays a tribute to the intuitive sense that observations (P concentration in the soil) that are closer together are more related (more similar) than observations that are further apart. The underlying assumption is that the phenomenon studied is one possible outcome of an unknown environmental process (random function). It is the modeling of the random function, which is the core of geostatistics.

Modeling of the Random Function

The random function can be modeled by recognizing explicitly the spatial correlation between the data. The classical geostatistical approach is to use the semivariance:

$$\gamma(h) = \frac{1}{2} E \left[\left\{ Z(x) - Z(x+h) \right\}^2 \right] \quad (1)$$

where E signifies expectation, and h is the vector, the so-called “lag,” separating the two points x and $x+h$.

The semivariance, which is only dependent on the distance h and not on the positions x and $x+h$, is a measure of the average degree of dissimilarity between two observations, e.g., the P concentration at point x and the P concentration at point $x+h$.

Fig. 1 Various views of spatial continuity and their relationships. The “sample map” (A) can be used to identify errors in the coordinates and data clustering. An “h-scatterplot” (B) is the bivariate equivalent of the histogram. The value of one variable at position x is plotted against the value of the same variable at position $x+h$. “The variogram map” (C) is a 2-D plot of the experimental semivariogram values in the system of coordinates (h_x, h_y) . When the variation is isotropic, the increase is fairly similar in every direction; hence, the map shows concentric contour lines. Conversely, geometric anisotropy appears as elliptical contour lines whose major axis indicates the direction of maximum continuity. “The experimental semivariogram” (D) that forms the basis for the modeling of the random function.

Source: From Pannatier.^[5]

By plotting the semivariance against the distance h , one obtains the experimental semivariogram, often just referred to as the variogram (Fig. 1). Because the underlying processes that govern the spatial distribution of data often have preferred orientations, data may change more quickly in one direction than in another. Thus, the variogram is a 3-D function, consisting of two independent variables, namely the direction and the distance h , and one dependent variable, the observation $z(x_i)$. Distributions that have preferred orientations are called anisotropic, whereas otherwise they are referred to as isotropic. A useful tool to assess the orientation of the soil property of interest is the so-called “variogram surface.”

To detect the random function that caused the spatial dependency of the observations, it is necessary to fit a model through the experimental variogram. There are

certain restrictions on the functions that can be used to model the experimental variogram.^[6] The most common permissible models are illustrated in Fig. 2. The spherical model is probably the most commonly used model. It has a simple polynomial expression, and the shape matches well with what is often observed: an almost linear increase in the semivariance up to a certain distance and then stabilizing. The exponential model rises more rapidly initially and reaches the so-called “sill” asymptotically. The Gaussian model represents an extremely continuous phenomenon, such as soil water content. In contrast to the above-described models, the power model, with the linear model being a special case, is not bounded^[6] and indicates an underlying trend or drift in the data.

The nugget variance C_0 represents the random variation of the data set that arises first from measurement error and

Fig. 2 Permissible variogram models. Bounded models with the same practical range (top graph) and power models for different values of the parameter α (bottom graph).

Source: From Goovaerts.^[6]

second from a spatial variability at distances smaller than the shortest sampling interval. The structural semivariance C_1 represents the component of total variation that is contributed by systematic sources. The sill is the plateau every bounded model will reach. The sill gives an estimation of the total variance (random + structural) of the data.^[7] The distance at which the model reaches the sill is called the “range.” All data within this range are assumed to be spatially autocorrelated (Fig. 3).

A quantification of the contribution of the random variation to the semivariance observed in a data set can be estimated from the ratio of nugget semivariance to sill semivariance:^[8]

$$NR = \frac{C_0}{C_0 + C_1} \times 100 \quad (2)$$

This ratio has been used to describe the strength of the spatial dependence within a field attribute^[9] where:

NR ≤ 25%: indicates a strong spatial dependency

25 < NR < 75%: indicates a moderate spatial dependency

NR ≥ 75%: indicates a weak spatial dependency

(3)

The variogram parameters, nugget, sill, and range form the basis for all further geostatistical processes, such as kriging

Fig. 3 Spherical model with nugget effect fitted to the experimental variogram for soil pH in Warburg, Germany (E10°54', N52°10').

or simulations. Thus, the correct modeling and interpretation of the variogram are extremely important. As an excellent guide to variogram modeling, the reader is referred to Gringarten and Deutsch.^[10] Although the calculation of experimental variograms and subsequent fitting of appropriate variogram models is the most common method to model spatial patterns, there is no general agreement on how to evaluate the goodness of the chosen model. There is a tendency within the geostatistic community to justify the choice of a particular model using statistical criteria such as the weighted least squares criteria,^[11] cross-validation,^[12,13] and the indicative goodness of fit.^[5] The disadvantage of these statistical criteria is that they purely rely on the experimental variogram without taking any ancillary information into account. As with any model, the outcome of the variogram model has to be an approximation toward the truth,^[14] and thus, it has to reflect physical knowledge of the area and of the phenomenon under study. Ancillary data that can be utilized to improve the model are topography, distribution of different soil texture classes, and geological formations as well as management practices.^[15]

APPLICATION IN SOIL SCIENCE

Optimal Interpolation and Isarithmic Mapping of Soil Properties

Where measured data are sparse, as they often happened to be, it is necessary to predict observations at unsampled locations. Several interpolation techniques have been proposed, but kriging is the only technique that not only minimizes the error of interpolation but also evaluates it.^[2] The kriging principle consists of determining the weights of the variable values in neighboring points to estimate the variable value in the target point or spatial domain. The weight of each point is determined from the variogram. The weights are selected to obtain an unbiased estimate

Fig. 4 With a spherical model of range $a/L=2$, the remote samples get lower weights. Z at the unsample location x_0 will be estimated according to $\hat{Z}_0 = \sum_{i=1}^N w_i Z_i \Leftrightarrow \hat{Z}_0 = 40.6\% \times (z(x_1) + z(x_3)) + 9.4\% \times (z(x_2) + z(x_4))$.

Source: From Wackernagel.^[16]

(all weights sum up to 1) of the target value and the minimum variance of the estimate:

$$\sigma_E^2 = E\left\{\left[Z_0 - \hat{Z}_0\right]^2\right\} \quad (4)$$

The closer the specific testing site to the point or domain for which the parameter should be determined, the more substantial is its contribution to the target value (Fig. 4).

Optimizing Sampling Schemes

For most soil surveys, the limiting factors for obtaining sufficient data are the costs and manpower involved in sampling and subsequent analysis of samples. Prior knowledge of the within-field variability of the soil property of interest is essential to optimize full-scale sampling. Several papers suggested determining the variogram for the property in a prior reconnaissance stage of a survey. Once the maximum permissible variance for the survey has been determined, the optimal sampling interval is easily obtained from the variogram.^[17,18] As the amount of samples needed to estimate a variogram in advance of full-scale sampling can be a “serious obstacle,” McBratney and Pringle^[19] proposed the use of proportional variograms, whereby the variogram can be predicted from a mean value.

Uncertainty Analysis

The quality of spatial soil data modeling is subjected to two kinds of uncertainty. The first type, local uncertainty,^[6] addresses the quantification of the precision of interpolated estimates, whereas the second type, spatial uncertainty,^[6] is a measure of the joint uncertainty about the outcome of a soil property analysis at several locations taken together. Local uncertainty is often estimated based on the kriging variance.^[6,20,21] However, it can only be used as a measure of reliability of the kriging estimate whether the variance of the errors is independent of the actual data values and depends only on the data configuration, a situation referred

to as “homoscedasticity.” As this requirement is hardly ever met in soil data, a more popular approach is to use indicator kriging.^[22–24] To give credit to the inherent local variability of the data and the spatial uncertainty, a process known as stochastic simulation has become more popular than kriging.^[25] The principle is to perform variogram modeling and subsequent kriging of the data at all grid locations to obtain a “base” map. In simulation, the objective is to generate multiple realizations of this base map each of which would honor the actual data (i.e., a conditional map), and approximately the same variogram and distribution. The key is to generate a high number of realizations (repetitions) such that the simulation results are truly representative of the stochastic nature of spatial heterogeneity and uncertainty (refer Heuvelink and Burrough^[26] also).

CONCLUSION

Scientific knowledge is based on the interaction between observations and the hypothesis that corresponds to those observations. Soil science is increasingly asked to answer questions like how do soils function in environment and how will they function and respond to a changing environment. The classical description of soil does not provide the answer. Geostatistics offers a range of tools that allow the modeling of soil functions and the interpretations of the outcome. For a range of applications such as optimal interpolation of soil properties, optimizing sampling schemes, and uncertainty analysis, to name only a few, geostatistics is essential to obtain the maximum information contained in observations and thus should be an integrated part of modern soil science.

GIS Integration: Remote Sensing

Egide Nizeyimana

*Department of Agronomy and Environmental Resources Research Institute,
Pennsylvania State University, University Park, Pennsylvania, U.S.A.*

Abstract

Remote sensing (RS) is often viewed as technology for data acquisition on the earth's surface. This entry provides ways in which RS, including aerial photography, is integrated to a geographic information system (GIS) for environmental assessments needed in land use planning and management. RS is compatible with GIS because the data generated are geo-referenced to a known coordinate system and are spatial in nature. These data are generally stored and queried as grid, a data structure supported by the most popular commercial GIS software. Later, they are transferred to a GIS platform after processing for integration with other spatial land attributes from spatial data sources such as soil databases and digital elevation models. This RS/GIS integration and associated data sets can also be part of GIS-based systems such as GIS/model interfaces and spatial decision support systems.

COMPATIBILITY ISSUES BETWEEN REMOTE SENSING (RS) AND GIS

A geographic information system (GIS) can be defined as a set of computer tools for capturing, storing, analyzing, and displaying spatially referenced data. The data within a GIS consist of two elements: spatial entities represented by points (e.g., well locations), lines (e.g., streams, road networks), and polygons (e.g., soil delineations) and attribute data or information that describes characteristics of the spatial features. The spatial entity is referenced to a geographic coordinate system and is stored in either a vector or raster model. GIS is primarily a platform that integrates spatial information from variable data sources and provides tools to overlay and analyze it.

RS is compatible with GIS because the information acquired by imaging sensors carried aboard satellites and airplanes is geographic in nature, referenced to a known coordinate system, and in a grid layout, a raster data model commonly found in most popular GIS software packages. In a raster model environment, the analysis is performed pixel by pixel. The commercial GIS-based software packages have vector and raster capability analyses and allow data conversion from one data model to the other. Non-imaging systems are also important to RS/GIS integration because they provide point data, which at geo-referenced locations are often combined with other environmental data for site-specific assessments.

LINKING RS AND GIS

RS as a Source of Spatial Data

RS is one of the most important sources of land use/cover information used in GIS analyses. It provides information

on the location and spatial and temporal distribution of land cover on the earth's surface. Land use/cover distributions may be derived from aerial photographs after they are corrected for relief displacement and distortions caused by camera angle and registered to a coordinate system. Delineations of different land use/cover types on photographs are made from visual interpretations of characteristics (e.g., tone, texture, and color) aided by optical devices. Digital maps of these classes are created by digitizing and processing boundaries between land uses or by scanning photographs covering the area of interest and screen digitizing their boundaries.

Land use distributions on the earth's surface may also be obtained using RS imaging systems. In this case, RS provides opportunities in the area of land use planning which would not be otherwise available. While aerial photographs are effective and appropriate for analyses of small areas, RS offers tremendous advantages when planning for large areas such as river basins and regions. The fact that the land surface is observed from reflected/emitted energy for large areas and over a wide range of wavelengths allows for easy differentiation of land uses (e.g., wetlands and degraded landscapes).^[1] Earth observation satellites also offer a repetitive coverage of the land, thus providing the possibility of monitoring land use pattern changes over time. Gathering information on land uses at several time intervals is particularly important in the monitoring and land evaluation stages of the land use planning process. Factors such as plant stress, crop growth and yields that serve as measures of agricultural productivity can be rapidly estimated following digital processing and analysis of RS imagery. RS has been used in many instances to monitor land surface conditions such as soil degradation and soil salinity.^[2] It is true that RS cannot replace field mapping of land use/cover. However, RS supplements provide

information that would not otherwise be available for land use planners and managers. There is no doubt that the development of sensors of high spatial resolution (1 m and higher) in orbits would increase the use of RS in land use planning and management.

As indicated before, RS and GIS technologies are highly compatible primarily because of the nature of RS as a source of spatial land use/land cover used in various environmental applications. Remote sensed imagery is a grid cell layer, a data format easily handled by GISs. In the RS/GIS integration, GIS appears as a platform that stores and integrates spatial data from different sources including RS and output information needed for environmental analyses depending on the type of analysis sought. Land use/cover distributions derived from RS are input to GIS, GIS-based systems (spatial decision support systems), and models (e.g., hydrologic/water quality, crop yields, primary productivity) commonly used in land evaluation for land use planning and management. GIS has been proven to be a valuable tool in integrating RS-derived data with climate and land surface parameters (soils, terrain, etc.) to generate digital maps of ecosystem productivity or vulnerability to environmental factors.^[3] The parameterization of the Terrestrial Ecology Model and a forest ecosystem model using GIS- and RS-derived data at regional scales has also been accomplished.^[4,5] The RS/GIS approach has been adopted by many state and federal agencies involved in environmental assessments. For example, in the GAP Analysis Program, the U.S. Geological Survey (USGS) and collaborative institutions map and/or model potential natural habitats of native vertebrate species from remotely sensed data across the country and use GIS map overlay tools to determine the degree of richness of habitats in these species.^[6]

Finally, GIS and RS applications have promoted the development of other high-resolution spatial technologies that enhance the land use assessment and planning. Some of these are the global positioning system (GPS) and digital orthophoto quadrangles (DOQ). GPS allows the user to record accurately and rapidly geographic coordinates of any location in the field with precisions ranging from several meters to a centimeter. Soil, terrain, and land use attributes observed or measured can then be input to a GIS along with their precise locations and extent. GPS coupled with a GIS can improve the accuracy of land quality mapping by increasing the spatial variability of soil and landscape attributes. DOQs, on the other hand, are digital images of aerial photographs that were corrected to remove relief displacement and distortion caused by the camera angle. The USGS distributes single-band, 256-scale, gray-scaled DOQs at 1-m grid resolution. Although DOQs have not been used extensively in land use planning, their high resolution and photograph-like characteristics make them a potential source of data in this area. Furthermore, repetitive DOQs acquired at different times can be used to monitor the magnitude of changes in land use over time. The relationship between GIS, RS, and other data sources is shown in Fig. 1.

Fig. 1 Relationships between RS and GIS.

Applications of RS/GIS in Soil Science

The need for geospatial data for use in various spatial database development and analyses in industry, government, and universities have increased the demand for remotely sensed data. In the area of soil science, the RS technology is used to acquire data and digitally process and analyze it. Subsequent analyses may involve error assessment, and data conversion from raster to vector format and vice versa before the data is merged with other data sets in GIS for specific analyses. Table 1 summarizes RS techniques used in various aspects of soil science and potential limitations for use in GIS and advantages of each. These are laboratory approaches, field methods, and aircraft-/satellite-based methods. The latter involves interpretation and analyses of digital images, color composites, or radiances.

RS/GIS Integration for Site-Specific Farming (SSF)

The goal of SSF or precision farming is to optimize the profitability of a farm practicing variable management according to soil conditions found at each site. The concept is based primarily on the fact that soil chemical and physical properties that affect crop production (e.g., pH, nutrients, available water, and impeding layers) vary spatially across agricultural landscapes. Management practices such as fertilizer and pesticide applications, irrigation water, and crop varieties should, therefore, be prescribed according to this soil variability. The profitability associated with variable rate applications of SSTs should avoid or reduce waste and the risk for environmental pollution because these

Table 1 Documented uses of RS in various areas of soil science.

Application	Advantages	Potential limitations	References
Laboratory methods	Provides accurate measurements of reflectance values	Provide point data rather than areal extent of soil properties	[8]
Field methods	Easily related to on-site conditions	Provide limited data coverage; measurements are affected by soil conditions (soil roughness and moisture), sun angle, etc.	[9]
Airborn-/satellite-based methods	Provides areal extent and temporal coverage of soil properties	Radiance measurements affected by atmospheric and soil surface conditions	(–)
a) Interpretation of digital images	Good results when data are well analyzed and interpreted	Image analysis can be costly; requires experienced technician for good results; field verification or prior knowledge of area required for best results	[10]
b) Interpretation of color composites	Easy to use and rapid interpretations	Intensive field verification is needed for good results due to the fact that interpretation is based on differences in tone and physical characteristics of objects; requires experienced interpreter for good results	[11]
c) Interpretation of radiances	Relatively easy, cheap, quantitative; data can be normalized to remove environmental effects	Results often unreliable	[12]

Source: Adapted from Nizeyimana & Petersen.^[13]

agrochemicals are applied to the field only in amounts needed for optimal crop growth.

In an SST, the real-time detection of continuous soil variable is made possible by mobile devices including sensors and differential GPS units, while agrochemicals are applied using variable rate field applicators mounted on farm equipments. These sensors are based on the same principles as RS and have been developed to detect, directly or indirectly, soil properties such as soil moisture, soil texture, nitrates, etc. The data acquired, along with their respective locations, are often integrated with spatial information from other sources such as soil databases, climate, landscape, and satellite/airborne RS to delineate meaningful management zones within the farm.

Abstract

For most purposes, the term biome is used to identify the natural habitat conditions around the world. Depending on the purpose, the global ecosystem is divided into units each characterized by a specific combination of climatic factors. Two major determinants of biome type are precipitation (total and its distribution) and air temperature. These two elements of climate have been commonly used to define the major biomes of the world. A third variable that affects the habitat type is the soil. This entry presents a general overview of the soils characterizing the major biomes of the world.

INTRODUCTION

A biome is defined as “a community of organisms interacting with one another and with the chemical and physical factors making up their environments.”^[1]

Detailed maps showing the biomes of the world are not available due to conceptual differences of definitions and reliable global databases. There are many excellent and detailed studies of specific habitats around the world, and using these and the global soils and climate database of the world,^[2] a map showing the distribution of the major biomes was drawn. The terms used to describe the biomes are common in use, but their subdivisions are based on important differentiating factors.

MAJOR BIOMES

The five major biomes of the world and their subdivisions are listed in [Table 1](#) and their distribution is shown in [Fig. 1](#). Some geographers have used elevation as a differentiating factor and recognized a “montane biome.” This biome’s small extent precludes its description in this section. Few geographers recognize the Mediterranean biome as presented here as a subdivision of the Temperate biome. Within each biome, some major distinction is made. In the Polar biome, an attempt is made to differentiate areas with permafrost and warmer areas with intermittent permafrost. The latter is termed “interfrost.” The Boreal Forest biome has a humid and a semiarid counterpart similar to the temperate and tropical zones. The semiarid vegetation is generally grass or shrubs. The desert areas are divided into hot, cool, and cold equivalents.

Deserts occupy about 30% of the global ice-free landmass. Potential evapotranspiration exceeds precipitation

during most days of the year, and the biome shows the greatest contrast in temperature, both diurnal and seasonal. Desert vegetation is very sparse with a few isolated shrubs dominated by succulents and annuals. Grasses and forbs become more dominant at the margins. The tropics occupy about 27% of the landmass and are characterized by only a small variation in temperature during the year. The soil moisture conditions range from semiarid to humid. The availability of soil moisture determines the biota. The temperate grassland and forest biome occupies about 15%. The cold biomes, the boreal and polar, are mainly in the northern latitudes with small areas in South America. The low temperatures control the flora and fauna, and vegetation is scarce to non-existent in the extreme cold polar regions. Each of these areas has specific kinds of soils that have developed as a response to the specific soil moisture and temperature conditions. The diversity in vegetation has its equivalent in fauna with animal species adapting to the specific bioclimatic conditions. Within each of the biomes, there are specific conditions that promote unique flora and fauna. Examples of such localized systems are volcanic hot springs, wetlands, and oases.

Soils of the Major Biomes

Soil temperature and moisture, with their seasonal and annual variations, are an integral part of the soil classification system called Soil Taxonomy^[3] which is used here. As [Fig. 1](#) and [Table 1](#) are based on soil moisture and temperature conditions, there is an implied link between the biomes and their soil resource endowments. The purpose of this introductory section is to present the general geographic distribution of the biomes and the major soils characterizing each. The major soil orders are listed in [Table 2](#).

Table 1 Major global biomes with subdivisions and their areas

Global land area					
Biome	Subdivision	Remarks	In thousand km ²	In%	In%
Polar	Permafrost	Mosses and lichens	10,547	8.06	15.46
	Interfrost	Shrubs and stunted trees	9,685	7.40	
Boreal	Semi arid	Shrub	3,552	2.72	9.94
	Humid	Forest	9,446	7.22	
Temperate	Semiarid	Grassland	7,348	5.62	15.14
	Humid	Forest	12,453	9.52	
	Mediterranean warm	Shrubs and forest	3,624	2.77	3.37
	Mediterranean cold	Forbs and shrubs	791	0.60	
Desert	Hot	Barren	4,418	3.38	29.47
	Cool	Barren	28,521	21.81	
	Cold	Barren	5,599	4.28	
Tropical	Semiarid	Grassland, savanna	20,299	15.52	26.62
	Humid	Forests	14,514	11.10	
Total			130,796	100.00	

The subsequent sections elaborate on the soil resources of each of the six biomes listed in [Table 1](#).

Polar Biome

Characterized largely by a mean annual soil temperature of less than 0°C, the Polar biome occupies a large land mass

adjacent to the Arctic circle to about 60°N latitude. This is generally the ice-free land of the northern latitudes. The sub-zero soil temperatures that prevail during most of the year are conducive to the formation of permafrost. The dominant soils of the region are Gelisols, occupying 59% of the Polar biome. Turbels freeze and thaw once or more during a year which triggers cryoturbation or physical

Fig. 1 Major biomes.

mixing of the soil material. The orthels are generally shallower or drier soils and have little or no cryoturbation. The low temperatures and periodic moisture saturation promote the accumulation of organic matter. The histels are characterized by the high organic matter and occupy about 5% of the Polar biome. These organic soils form the largest contiguous extent of such soils in the world and serve as an important sink of carbon dioxide. Other soils that occur in the Tundra zone are Inceptisols 33% and Spodosols 6%, while Mollisols and Entisols are each 1% of the area.^[4]

Boreal Forest Biome

Bordering the southern flank of the Polar biome is the Boreal Forest biome in the northern hemisphere. The high volcanic area between Chile and Argentina has similar climatic regimes but the nature of the soil and physiography may result in a different set of habitat conditions. There are about 243,000 km² of Andisols or volcanic ash soils characterizing the Boreal Forest biome in the southern hemisphere. Such soils only occur as a small area in the Kamchatka Peninsula in the Northern Hemisphere. In Northern Europe and Siberia, the Boreal Forest biome has a humid part and is bordered in its southern periphery by a semiarid to arid part. In Canada, the semiarid part is in the middle of the continent. A range of soils are present, and the most extensive are the Spodosols, which occupy 2.7 million km² (20.6%). The Spodosols are mostly in the humid part of the Boreal Forest biome and form under acid vegetation. Histosols are present in the depressions in this cold region.

Temperate Grassland and Forest Biome

The Temperate Grassland and Forest biome extends from about 25 to 55°N with counterparts in the southern hemisphere. Large areas in this belt are also deserts. Due to the favorable climate and soil endowments of this biome, much of the land is used for agriculture and native habitats are local and sporadic. About 50% of the zone (12.1 million km²) is occupied by Mollisols and Alfisols (grasslands), and Ultisols in the forests. Their general good fertility and tilth have made them in great demand for grain production. Due to the long history of civilization in the Temperate Grassland and Forest biome of Europe and China, pristine ecosystems are rare. In large areas, there have been successive replacements and changes in the floral and faunal composition. Within the Temperate biome, are areas characterized by moist winters and dry summers. These Mediterranean conditions are conducive to unique ecosystems. These areas occur around the Mediterranean Sea and small areas in the Western United States and Southern Australia.

Desert Biome

Deserts occupy about 38.6 million km² and may be distinguished as warm (or tropical), cool (or temperate), and cold (or boreal) kinds of habitats. Although the biome is characterized by lack of moisture for normal vegetative growth of most plants, the ambient temperature conditions further distinguish the habitat conditions. About 38.6% of the Desert biome is occupied by Aridisols, which by definition have some kind of subsurface horizon. Shifting sands or moving dunes occupy about 13.7% and Entisols, which are deposits, occupying about 33% of the Desert biome. The harshness of the environment has resulted in plants and animals with special adaptive features. Many of the Aridisols are increasingly used for agriculture when irrigation facilities are made available. In this fragile ecosystem, both soil and habitat conditions are drastically altered when irrigation is introduced.

Tropics Biome

An absence of winter and summer temperature extremes characterizes the Tropics biome, which occupy about 34.8 million km². Availability of moisture separates the semiarid from the humid tropics. As a corollary to the desert, in the humid tropics there are the perhumid areas where the potential evapotranspiration never exceeds the precipitation during any month of the year. This is a biomic condition that deserves much greater detailed studies. The Tropics biome is the home to the Oxisols (9.6 million km²), which are unique to this biome. These are highly weathered soils where the original vegetation is closed or open forests. Most of the plant nutrients are concentrated in the top 5 cm of the soil and recycled through plant uptake and leaf fall. Ultisols also occur in this biome. Apart from these soils, there are small areas of most of the other soil orders. The wetlands of the tropics present a separate and unique habitat condition and those along the coast have some special soils.

Grass Strip Hydrology

Hossein Ghadiri

Faculty of Environmental Sciences, Griffith University, Nathan Campus, Nathan, Queensland, Australia

Abstract

The zone of hydraulic adjustment or backwater is a zone of considerable deposition from sediment-laden flow. The efficiency of the grass strips in slowing down the flow and unloading its sediment in the backwater region appears to be largely independent of the width of strips in the flow direction. The layer of deposited sediment formed in the backwater region tends to be richer in larger particles than the eroding sediment. Sediment size distribution appears to be a dominant factor governing the efficiency of the buffer strip in trapping sediment. Soil-sorbed nutrients and other agricultural chemicals are mainly attached to finer soil particles, which are more likely to pass through the strips largely unchanged. Thus the sediment that emerges from a buffer strip can be enriched in such chemicals relative to the eroding soil. Hence although buffer strips can be very efficient in forcing the deposition of suspended sediment in the backwater region on certain slopes, they are helpful, but less effective, in preventing chemical pollutants from entering surface water bodies.

INTRODUCTION

The use of vegetated strips is one of the simplest and most widely employed methods of reducing the flux of eroding soil and associated chemicals across slopes (Fig. 1) and into streams. Grass strips of various type, width, spacing, density, rigidity, and strength have been used for soil erosion control on sloping lands and for water quality control in riparian zones with varying degrees of success.^[1–3] It was widely believed, with some support from field studies, that the effectiveness of buffer strips in sediment trapping was largely because of a filter-type action, with strips filtering out the suspended sediment as runoff passes through them, leaving the emerging runoff significantly cleaner in terms of sediment, nutrients, and soil-sorbed contaminants. Because of such perceived mode of operation, buffer strips have been commonly referred to as “filter strips.”^[4,5] However, studies have shown that a filtering action is not a major contributing process to buffer strip effectiveness. Considerable experimental evidence in the literature suggests little or no net deposition within the buffer strips.^[6–9] Some have reported the occurrence of erosion, rather than deposition, inside the grass strips.^[4,8]

Studies have sought to understand the mechanics of flow through grass strips, seeking the real reason for the inconsistencies observed in their effectiveness.^[2,7–11] It has been recognized that a flow-resistive element such as a cross-slope strip of vegetation modifies the hydrology of overland flow, and that this modification has implications for

the transport and deposition of sediment and associated nutrients in and around the strips.^[7,8,11,12] It is the hydraulic consequence for overland flow when it meets and flows through a resistive element, which first needs to be understood to ascertain the effectiveness, or otherwise, of grass strips in reducing erosion, enhancing deposition, and reducing the transportation of pollutants into surface water bodies. Such understanding is also necessary for the development of models and the prediction of buffer strip effectiveness under different conditions. This entry covers the progress made in this area.

EFFECT OF BUFFER STRIPS ON FLOW HYDRAULICS

One of the main hydrologic features of flow through grass strips is the formation of a pronounced backwater,^[8] or a zone of hydraulic adjustment.^[9,13] The length of this zone appears to be dependent on land slope, strip density, and flow rate (Fig. 2). At any constant flow rate, the length of backwater *B* has been shown to be linearly related to the ratio of strip density over slope:

$$B = k \frac{D}{S} \quad (1)$$

where *k* is a proportionality constant, *D* is percent grass coverage in the strip, and *S* is slope. Eq. 1 shows that decreasing density and increasing slope both have the effect

Fig. 1 Strips of Vetiver grass used as a soil erosion control technique in Queensland, Australia.

Source: Photo courtesy of Mr. Cyril Ciesiolka of DPI, Toowoomba, Queensland, Australia.

of decreasing backwater length^[8] (Fig. 3). The starting point of the backwater region is a hydraulic jump, which moves closer to the strip as the slope increases or as the grass density decreases.

The front edge of the backwater is usually sharp and clear at high slopes (Figs. 2 and 3), getting less distinct as it moves away from the strips with decreasing slope or increasing grass density. At low slopes of around 1%, the front edge of the backwater breaks into a number of waves. The width of the strips does not appear to play an important role in backwater formation or its characteristics.^[8]

Theoretical interpretations of flow through grass strips are very few. However, there is a long history of investigation of hydraulic jumps in the hydraulic literature. Chow^[13] developed the hydraulic jump theory for deep rectangular

channel flow encountering solid barriers such as dams and weirs. This interpretation does not apply to our condition of shallow unconfined flow being partially blocked by porous barriers such as grass or nail strips. Rose et al.^[9] have shown that the change in hydraulics because of the presence of a buffer strip can be understood in terms of the conservation of momentum theory.

EFFECT OF BUFFER STRIPS ON SEDIMENT TRANSPORT

Runoff sediment concentration results from the balance of two quite rapid processes, such as, entrainment (or re-entrainment) by the overland flow and deposition. Even a

Fig. 2 Illustrating flow and sediment deposition in the backwater region of a barrier strip.

Fig. 3 Effect of slope on the length of backwater (flow height recorded digitally; flow is from left to right and the two long vertical lines on each trace show the beginning and the end of the grass strip).

modest reduction in flow velocity in the backwater region produced by the vegetation buffer strips reduces the entrainment rate, resulting in net deposition in this region. Thus the effect of grass strips on erosion/sedimentation is mainly through their impact on surface hydrology.

Net deposition of coarse sediment load commences at the starting edge of the backwater (or at the hydraulic jump) (Fig. 2). This site of initial net deposition approaches the strip with an increase in slope, or a decrease in strip density, eventually burying and entering the strip. Sediment deposition generally follows the hydrologic pattern established at the early stages of the flow, as predicted by Eq. 1.

Little, if any, deposition appears to take place inside the strips prior to the point of grass collapse.^[6,8,14] Sediment that deposits in the backwater moves into the strip zone only after burying the first few rows of the vegetation.^[2] The unburied rows then become the new front edge of the strip. However, once the first rows of the strips give way, the process usually continues until the entire width of the strip collapses at one point or more (Fig. 4).

Many researchers have reported that the width of the grass strip has little effect on the efficiency of the strips in slowing down the flow, or unloading its sediment content.^[2,15] However, there are others who have reported

Fig. 4 Collapsed grass strip on 8% slope (flow from left to right; total collapse happened after the first few rows of grass were buried under the deposited sediment; vertical white bar is a 15-cm ruler).

the opposite.^[1,3] The disagreement between the two groups is yet to be resolved.

THEORETICAL INTERPRETATION OF SEDIMENT TRANSPORT THROUGH BUFFER STRIPS

Mass conservation of deposited sediment was used by several researchers^[16,17] to describe the resulting change in the shape of the deposited layer. However, their models do not represent the hydrology and net deposition upslope of the grass strips (Fig. 2), and only deal with single-size particles. A more appropriate theoretical explanation of flow through porous barriers is given by Rose et al.,^[12] who showed that the appropriate equation to solve (under steady flow conditions) is as follows:

$$\frac{\delta}{\delta t} M_{di} = -q \frac{dc_i}{dx} = d_i - r_{ri} \quad (2)$$

where t is time, M_{di} is the mass per unit area of sediment of size class i in the region of net deposition, q is volumetric water flux, c_i is sediment concentration of size class i , x is downslope distance, d_i the rate of deposition per unit area, and r_{ri} is the rate of re-entrainment of newly deposited sediment of size class i .

EFFECT OF BUFFER STRIPS ON CHEMICAL TRANSPORT

Soil chemicals are preferentially sorbed to the finer fractions of soil.^[18,19] Buffer strip influences the transport of sorbed chemicals mainly through sediment sorting processes, which take place in the backwater. Sediment passing through the strips is significantly finer than that initially dislodged by the flow. It was shown by Ghadiri and Rose^[19] that the concentrations of organic matter, sorbed nutrients, and agricultural chemicals can be significantly higher on the finer particles. The preferential deposition of larger aggregates and particles in the backwater leaves the sediment, which emerges from the buffer strip, relatively enriched in fine particles and thus in soil-sorbed chemicals. Such transmitted fine particles, together with their chemical load, may stay in suspension until entry into receiving waters. Therefore, grass strips are less effective in reducing overland transport of solutes or solids-associated chemical pollutants than they are in reducing sediment load.

CONCLUSION

Buffer strips behave like porous barriers against flow, creating backwater regions upslope of the strips with reduced flow velocity and increased depth in a length that varies with slope, strip density, and flow rate. For a constant flow rate, there is a linear relationship between

backwater length and the ratio of strip density over slope. Momentum theory appears to provide a reasonably good prediction, both of the shape of the water profile within the strips, and of the slope and extent of backwater region.

The zone of hydraulic adjustment or backwater is a zone of considerable deposition from sediment-laden flow. The efficiency of the grass strips in slowing down the flow and unloading its sediment in the backwater region appears to be largely independent of the width of strips in the flow direction. The layer of deposited sediment formed in the backwater region tends to be richer in larger particles than the eroding sediment. Sediment size distribution appears to be a dominant factor governing the efficiency of the buffer strip in trapping sediment. Soil-sorbed nutrients and other agricultural chemicals are mainly attached to finer soil particles, which are more likely to pass through the strips largely unchanged. Thus the sediment that emerges from a buffer strip can be enriched in such chemicals relative to the eroding soil. Hence although buffer strips can be very efficient in forcing the deposition of suspended sediment in the backwater region on certain slopes, they are helpful, but less effective, in preventing chemical pollutants from entering surface water bodies.

Grasslands Soils

Douglas D. Malo

Biostress Center of Excellence, Brookings, South Dakota, U.S.A.

Abstract

Soils and plants interact and evolve together forming different ecosystems. These soil–plant relationships are often most strongly expressed when native vegetation is present. The soils in grasslands, a major ecosystem, are very different from other soils due to this interaction.

INTRODUCTION

Soil science developed in response to problems. In Europe during the 1800s, food shortages, social upheavals, and declining soil productivity brought about the need to study soil to improve and increase its productivity. At the same time, in Russia, a need arose to administer and manage geographically diverse soil resources. Russia had large areas of fertile, productive soils unlike those in Europe. As a result, Russian scientists developed an inventory of agricultural resources and determined the factors causing soils to vary across Russia. Soils were found to have relationships with climatic and vegetative zones.^[1] It is from these concepts that the living soil individual was developed. Soil is a natural body and not a geologic formation. With time, soil develops from the parent material under the influence of the climate, vegetation, and topography (relief). These five factors of soil formation are interdependent and not independent. Changing one soil-forming factor often changes other soil-forming factors. Changing any one, some, or all of the soil-forming factors causes differences in soils and soil profiles.^[2]

IMPORTANCE, LOCATION, AND EXTENT OF GRASSLAND SOILS

Grassland soils have thick, dark-colored, humus-rich, surface horizons, or layers and are some of the most productive soils in the world. These soils occupy about 7% of the world's land area (Table 1). The majority of grassland soils occur in temperate (3.4%) and boreal (3.2%) regions.^[3] These soils are the dominant food- and fiber-producing soils in subhumid and semiarid regions because of favorable soil properties and climatic conditions. The world's breadbaskets (e.g., U.S. Midwest and Great Plains prairies; Canadian prairie provinces of Manitoba and Saskatchewan; the pampas of Argentina, Paraguay, and Uruguay; and the steppe regions of Europe, Russia, Mongolia, and Northern China) are dominated by grassland soils (Fig. 1). The largest grassland area in the world is found in Kazakhstan,

Russia, and the Ukraine. Generally, small grains and grain sorghum are raised in the drier grassland regions. The warmer, humid grasslands are better suited for row crops such as maize (corn) and soybeans. Where slopes are too great for cultivation or the climate is not favorable, grassland soils are used for pasture and rangeland. Native grassland types include: desert grasslands, <15 cm high; short-grass prairie, 15–30 cm high; mid-grass prairie, 30–100 cm high; and tall-grass prairie, 1–3 m high.^[7]

Grassland soils (e.g., Mollisols) are very extensive in the United States (Fig. 2), especially the Midwest and Great Plains. They occupy about 21.5% of the U.S. land area,^[3] more than any other soil ecosystem.

Grasslands tend to occur in subhumid to semiarid regions, where average annual precipitation ranges from 20 to 90 cm and average annual temperatures range from 0°C to 32°C.^[9] Grasslands tend to be located in areas between deserts (e.g., Aridisols) and forested (e.g., Alfisols) areas.^[3] Different climates with similar effective annual precipitation levels (e.g., prairies of California and western Kansas) give rise to grassland soils with similar properties.^[10] Soil texture and topography do modify the boundaries between prairie, forest, and desert areas (e.g., sandy, south-facing slopes are drier than loamy, north-facing slopes).^[11]

PROPERTIES OF GRASSLAND SOILS

Soils that form under grass vegetation have unique soil properties and characteristics (Table 2). Grassland soils (e.g., Houdek soil—fine-loamy, mixed, superactive, mesic Typic Argiustoll) have thick, soft, dark-colored, moderately high organic carbon-containing A horizons (e.g., 0.5–10% organic carbon) with developed structure (e.g., mollic surface). Granular structure is most common in surface horizons with blocky (humid areas) and prismatic (semiarid areas) structure present in B horizons. Cultivation often causes granular surface soil structure to change to subangular blocky.^[13] Grassland soils have sufficient strength to support grazing livestock and normal

cultivational activity. The dark-colored A horizon slowly changes into a B horizon in most prairie-derived soils (Fig. 3).

The Houdek Bt horizon has developed structure and evidence of clay illuviation (Table 2). Clay illuviation is much less than that found in comparable forested soils. Base saturation and soil pH are high in all layers of most grassland soils. Divalent cations, especially Ca^{2+} , dominate the soil-cation exchange sites. Most grassland soils have smectite (2:1 lattice silicate clay minerals) present in the clay fraction, and textures are usually finer than loamy fine sand.^[14] The average cation-exchange capacity of the soil solum is at least $15 \text{ cmol}_c \text{ kg}^{-1}$ but averages $25\text{--}35 \text{ cmol}_c \text{ kg}^{-1}$. Grassland soils can have many types of B horizons. Soils of the steppes tend to have horizons of lime accumulation (Bk in Fig. 3), whereas the grassland soils in humid areas tend to lack horizons of lime accumulation but have argillic, Bt, horizons.

Some grassland soils have pans (e.g., duripans, petrocalcic layers), and some have strongly developed eluvial, E, horizons (e.g., albic). Still other grassland soils have only weakly developed B horizons (Bw and Bg) or no B horizon at all.

GENESIS OF GRASSLAND SOILS

The genesis of grassland soils is strongly dependent on the vegetation. Grasses, a source of organic matter and nutrient cycling, provide these two key components to the soil body. The principal process in grassland genesis is the accumulation of high base-content humus in the soil from the dense grass root systems near the soil surface.^[2] Through the microbial decay of plant roots and plant tissue, organic matter is added to the soil surface and the soil profile in

grasslands. Soil macrofauna (e.g., earthworms) incorporate the aboveground biomass tissue into the soil surface and help increase surface organic-carbon levels. Most grass roots are found in the top 30 cm of grassland soils.^[15] Each year more than 50% of the biomass produced by unharvested grasses (nearly all of the aboveground biomass and about 30% of the below-surface biomass) is added to the soil.^[16] The amount of aboveground grassland-biomass production can range from 1500 to 3500 kg ha⁻¹ yr⁻¹, dry weight.^[2] The amount of air-dry organic matter added per year can vary depending on climate conditions and vegetation type (e.g., 1250 kg ha⁻¹ for humid prairie areas to 600 kg ha⁻¹ for short- to mid-grass prairies).^[17]

The distribution of organic carbon in grassland soils shows a gradual decline with increasing soil depth due to the gradual decline of fibrous grass roots and microbial activities with increasing soil depth (Table 2). This pattern

Fig. 3 Typical Great Plains grassland soil (Houdek—fine-loamy, mixed, superactive, mesic Typic Argiustoll). Scale is in feet.

of organic-carbon distribution is strikingly different from that in forest-derived soils where the organic carbon is high in a thin surface horizon and low in the rest of the soil. As a result, the structural stability of grassland soil peds tends to be stronger than non-grassland soil peds. Humus is not very water soluble, so it tends to stay in one location unless there

is suspension or some mechanism for mechanical movement. The organic-carbon decline continues until the native rooting depth of the grasses is reached, and there is little or no organic carbon.

Grasses are large users of bases, especially calcium (Ca^{2+}). As a result, when grass residue is added to the soil surface, large amounts of cations (Ca^{2+} , Mg^{2+} , and K^{1+}) are brought to the surface, replacing cations lost by leaching and weathering activities. This results in higher soil pH values and base saturation throughout the profile (Table 1). The high concentration of bases helps, along with the high content of shrinking–swelling silicate clay minerals and high humus levels, to form the granular structure that is common in grassland soils. In general, leaching under grass vegetation is minimal when compared to other types of vegetation (e.g., forest). Deep percolation of precipitation to the water table is not common, and deep leaching is not usually evident in most grassland soils. Grasses tend to utilize the water in the soil, preventing the deep leaching of nutrients. The grass plants keep recycling bases to the soil surface and this limits soil acidity, clay illuviation, and base-saturation reductions.

The development of textural horizons and silicate clay illuviation in grassland soils tends to happen in three steps:^[18]

1. Removal of free carbonates: as long as free lime is present, the soil remains flocculated and little or no silicate clay will translocate.
2. Silicate clay formation and alteration: silicate clays are formed and altered as a result of weathering and soil genesis.
3. Silicate clay eluviation and illuviation: the fine silicate clays ($<0.2\ \mu\text{m}$) move and precipitate out lower in the soil profile. The place where silicate clay illuviation occurs depends on pH, lime content, microbial activity, and moisture levels. Often, joint illuviation of both silicate clays and humus in grassland soils forms organo-argillans.

Another key indicator of soil genesis in grassland soils is phosphorus. Significant differences in phosphorus species have been noted in different grassland soils. Semiarid grasslands (Ustolls or Chestnut soils) had a larger percentage of calcium phosphates when compared to humid grasslands (Udolls or Chernozems), whereas humid grasslands had a higher percentage of iron phosphate.^[19] Phosphorus distributions (total, organic, and inorganic) within the soil profile depend on horizon, lime illuviation, vegetation, and drainage.^[18]

With cultivation in grassland soils, significant changes occur in the soil. Significant organic-carbon losses ($>20\%$ reduction in organic C levels after 20 years of cultivation) and soil quality reductions occur.^[7] The losses are most dramatic in the soil surface and diminish with increasing soil depth.^[18]

CLASSIFICATION OF GRASSLAND SOILS

The classification of grassland soils with various soil-classification systems is given in Table 3.

CONCLUSION

Throughout the world where grasslands are located, developed cultures exist. These soils are extremely productive and have allowed societies to flourish. About 40% of the grasslands are tall-grass prairies and 60% are short- and mid-grass steppes.^[7] Grasslands have higher organism activity than most other soils.^[9] Carbon sequestration in grasslands is critical to the global warming process. Grasslands are not only important for food and fiber production, but they have the potential to help solve one of the major problems facing human survival, global warming.^[6] Grasslands are one of the most important ecosystems in the world.

Abstract

Livestock production is responsible for most of the agricultural emissions, with about 22% from enteric fermentation, 10% from managed waste, and 18% from grazed lands. Grazing lands can be both sources and sinks of greenhouse gases (GHGs) as a consequence of vegetation and soil biological processes resulting in the transformation of carbon (C) and nitrogen (N) compounds into GHGs. This entry addresses in detail the factors influencing gaseous emissions, the types of gases produced, and the different management practices to decrease these emissions from grazing lands. Of the GHG emissions from grazed lands, 98% is in the form of nitrous oxide and the remaining 2% is methane. Although grazing lands are considered to be carbon dioxide (CO₂) neutral, they have the potential to store over 100 Tg CO₂ yr⁻¹. Gaseous production from grazing land is sporadic in both time and space, and so it is a challenge to scale up the measurements of gaseous emissions from a given location and time to regional and national levels. The exact approaches also depend on local conditions and therefore may vary from region to region.

INTRODUCTION

Grazing lands can be both sources and sinks of greenhouse gases (GHGs) as a consequence of vegetation and soil biological processes resulting in the transformation of carbon (C) and nitrogen (N) compounds into GHGs. In grazing systems, C and N can be exchanged in many forms among atmosphere, plant, soil, and animal components. Since the 19th century, carbon dioxide (CO₂), nitrous oxide (N₂O), and methane (CH₄) emissions have increased by 36%, 18%, and 148%, respectively.^[1] Although varied among years, the atmospheric concentrations of N₂O and CH₄ have increased by 4.9% and 14.9%, respectively, between 1990 and 2009.^[1] Globally, grazing lands and pasture cover about 3.6 billion ha or 8.9 billion acres, representing 27% of the world land area (13 billion ha) and 70% of the world agricultural area (5.2 billion ha).^[2] Broadly, grazing lands can be of different types, e.g., pasture lands, meadow, and rangelands (namely grasslands, shrublands, and savannas). Grasslands are particularly important sources of N₂O

emissions, which are greater in grazed (pastures) grasslands than in mowed (ungrazed) grasslands. Livestock grazing can increase C and N cycling by consuming crop and weed residues and returning C and N inputs into the soil through manure (feces and urine).

Livestock production is responsible for most of the agricultural emissions, with about 22% from enteric fermentation, 10% from managed waste, and 18% from grazed lands.^[3] Livestock manure is unmanaged when it is deposited directly on grazed lands. Alternatively, livestock manure can be managed in storage and treatment systems. Of the emissions from grazed lands, 98% is in the form of N₂O. The remaining 2% of GHG emissions from grazed lands is CH₄.^[3] N₂O, whose emissions into the atmosphere are influenced by the management of croplands and grazing lands, has a lifetime of approximately 120 years and contributes 6.24% to the overall global radiative forcing.^[4] There exists a positive correlation between CO₂ and N₂O, i.e., similarity in the rates of gas accumulation and diffusive flux due to soil moisture.^[5] By employing proper

management techniques, grazing lands can both sequester C and reduce emissions of CO_2 , CH_4 , and N_2O , thereby reducing their GHG footprint. This entry addresses the types of gases produced from grazing lands, the factors influencing these gaseous emissions, and the different mitigation strategies to reduce these losses.

DIFFERENT GASES PRODUCED FROM GRAZING LANDS

Nitrous Oxide

Grazed lands emit N_2O due to enhanced N cycling. Globally, livestock grazing is estimated to contribute about 1.55 Tg of N_2O -N flux yr^{-1} .^[5] N loss through volatilization during cattle grazing is ~ 20 Gg N. Unlike the case of CO_2 and CH_4 , there are no significant biological sinks of atmospheric N_2O . N_2O emission is predominantly from grazing lands amended with N-rich inputs such as synthetic and organic fertilizers, sewage sludge, compost, unharvested crop residues (both aboveground and below-ground), and manure.^[4] Grazing in grasslands reduces N uptake by plants, leading to the temporary accumulation of mineral forms of N in the soil. Increase in mineralization of soil organic matter (SOM) may release inorganic N in the soil, thereby stimulating microbial activity that

produces N_2O .^[5] A portion of the N cycled within the plant–animal–soil system volatilizes to the atmosphere in various gaseous forms and is eventually redeposited onto the soils where it can contribute to indirect N_2O emissions. N_2O gas is produced near the soil surface and is accompanied by a net increase in soil nitrate (NO_3^-). Some N in the form of NO_3^- can leach into groundwater and surface runoff, undergo denitrification, and also contribute to indirect emissions.^[3]

Mechanism of N_2O production

N_2O is produced in soil by the microbial action during autotrophic aerobic nitrification and subsequent heterotrophic anaerobic denitrification processes, which are affected by soil and climatic factors such as composition and availability of organic matter (OM) as a source of energy, decomposable organic C, N substrate supply or soil NO_3^- concentration, partial pressure of oxygen (O_2), O_2 supply, temperature, soil pH, soil enzyme activities, rainfall/irrigation, water-filled pore space (WFPS), and salinity. N_2O is a by-product of the first step of nitrification, whereas it is an intermediate or end product in denitrification. Although N_2O production by nitrification is possible, the N_2O emission peaks in grazed pastures are generally attributed to the denitrification process. Fig. 1 shows the N cycle for grazing lands.

Fig. 1 N cycle for grazing land.

Nitrification. It is a two-step process in which ammonium ion (NH_4^+) is oxidized to nitrite ion (NO_2^-) by two groups of nitrifiers, i.e., ammonia (NH_3)-oxidizing bacteria (*Nitrosomonas* spp., *Nitrospira* spp., and *Nitrosolobus* spp.) and NH_3 -oxidizing archaea (*Nitrosopumilus maritimus* and *Nitrososphaera viennensis*). During the second step, NO_2^- is oxidized by nitrite-oxidizing bacteria (*Nitrobacter* spp. and *Nitrospira* spp.) to NO_3^- .

Denitrification. It represents sequential dissimilative microbial reduction of NO_3^- via NO_2^- to gaseous nitric oxide (NO), N_2O , and finally molecular dinitrogen (N_2) via four enzymatic complexes. It is the last step in the global N cycle by which fixed N is returned back to the atmosphere. Although denitrifying organisms normally respire and metabolize aerobically when O_2 is present, a lower partial pressure of O_2 causes them to use oxidized forms of N as alternative terminal electron acceptor in their respiration chain. Denitrification is the only biological process of N_2O consumption; however, this process usually produces more N_2O than it consumes because the denitrification sequence is usually incomplete, i.e., not all of the NO_3^- is reduced all the way to N_2 , resulting in two main denitrification products: N_2O and N_2 . This process is usually carried out by heterotrophic denitrifiers, e.g., Thermoproteaceae, Cytophagaceae, Corynebacteriaceae, Streptomycineae, Bacillaceae, Rhodospirillaceae, Rhodobacteraceae, Rhizobiaceae, Burkholderiaceae, Nitrosomonadaceae, Neisseriaceae, and Pseudomonaceae, which can reduce NO_2^- into N_2O or N_2 . Denitrification can also be contributed by several autotrophic (*Nitrosomonas europaea*) and heterotrophic (*Pseudomonas denitrificans*) nitrifiers.

Other Nitrogenous Emissions

After the addition of N to farms as animal excreta, fertilizer, crop residues, or biological fixation, it can be lost by gaseous emissions to the atmosphere as NH_3 , NO, N_2 , and other NO_x besides N_2O , by runoff or leaching of NO_3^- and by soil erosion. In well-aerated soils, NO emissions are several times larger than N_2O emissions. The emission of NO is the principal gaseous N loss mechanism during nitrification in soil.

Methane

Manure deposited on grazed lands (i.e., unmanaged manure) produces and emits CH_4 . CH_4 emissions from this source are relatively small, less than 3% of total grazed land GHG emissions, because grazed lands do not often experience the anaerobic conditions required for CH_4 production to exceed CH_4 uptake.^[3]

Carbon Dioxide

Although grazing lands are considered to be CO_2 neutral, with a small uptake of 0.2 Tg CO_2 eq. through sequestration

of CO_2 in soil organic carbon (SOC),^[3] these lands can be emission sources or net sinks for atmospheric CO_2 depending on whether C inputs to the soil from plant residues and manure exceed C losses from the decomposition of SOM. Grazed lands have the potential to store over 100 Tg CO_2 yr^{-1} .^[6] Permanent grasslands used as pastures, rangelands, and hayfields can maintain large soil C stocks due to several characteristics. Perennial grasses allocate a high proportion of photosynthetically fixed C belowground, which is sequestered in the soil as OM after the residue is returned to soil, maintain plant cover year-round, and promote the formation of stable soil aggregates. CO_2 is emitted from soils to the atmosphere through the decomposition of dead OM and respiration by roots and mycorrhizal fungi. Soil C level is determined by the balance between the amount of plant residue C added to the soil and the rate of C mineralized as CO_2 emissions in unmanured soil. Plant residues also vary in their inherent decomposability due to differences in their chemical characteristics. Alterations in plant residues also alter the soil microbial community, e.g., an increase in plant lignin content favors soil fungi and thus leads to enhanced soil C storage. Fig. 2 shows the C cycle for grazing land.

FACTORS AFFECTING GHG EMISSIONS FROM GRAZING LAND

Abiotic Factors

These include soil temperature, water content, pH, texture, weather patterns, and various farm management practices. Soil fluxes of GHGs are also affected by other factors including air temperature, precipitation, net primary productivity, soil respiration rates, substrate quality, soil physical and chemical properties, and rates of decomposition of OM.

Soil temperature

It is the main environmental variable controlling CO_2 emissions, while CH_4 is controlled primarily by soil wetness and anaerobiosis. N_2O emissions respond to both changes in soil temperature and wetness. The temperature effect is normally expressed as Q_{10} value, which corresponds to the increase of reaction rate due to the increase in temperature by 10°C . For N_2O emission, values vary between 2 and 10. Soil temperatures in rangelands vary considerably not only between seasons but also diurnally. The N_2O emissions show a diurnal cycle, varying with the temperature of surface soil. Peak N_2O emission rates occur in the afternoon and are minimum near sunrise. Temperature influences enzyme kinetics and metabolic turnover rates of nitrifiers and denitrifiers with optimum temperature at $30\text{--}35^\circ\text{C}$. Microbial activity, OM mineralization, urea hydrolysis, and nitrification are higher at higher temperature and higher soil

Fig. 2 C cycle for grazing land.

water content, thereby resulting in higher CO₂ and N₂O emissions.

Soil moisture

Soil moisture or WFPS effect is mostly indirect, as it influences the rate of O₂ diffusion into the soil and controls the intensity of aeration, thus determining the degree of anaerobiosis. The interaction between moisture and aeration in the soil matrix influences NO₃⁻ formation and its stability. The nitrification process occurs with WFPS at 35–60%, and NH₄⁺ should be available in the soil. At levels higher than 60% of WFPS, denitrification is the predominant source of N₂O emissions, due to N mineralization and hindered diffusion of O₂ into the soil, favoring the formation of anaerobic environments. N₂O emissions often increase with increasing aeration during drainage of anaerobic soils. With the soil moist to less than field capacity (60% WFPS), average daily emission can range from 6 to 25 g N ha⁻¹ day⁻¹.^[7] The magnitude of N₂O emissions may increase about 12-fold from pasture soils when WFPS increases from 60% to 80%.^[8]

Soil pH

Soil pH influences the rate of denitrification and the ratio of denitrification products, N₂O and N₂, and subsequent N gas emissions influence not only directly through the kinetics of denitrification reductases but also indirectly through its impact on composition and abundance of the denitrifier community.^[9] Under acidic pH, the activity of N₂O reductase is

lowered, and the synthesis of new N₂O reductase is inhibited, resulting in an increased accumulation of N₂O.^[9] In soils with higher pH values, the activity and synthesis of N₂O reductase are supported, and the N₂O/(N₂O + N₂) ratio is decreased and, therefore, more N₂ is produced.^[9]

Soil texture

CO₂ emission may increase with decreasing clay content due to increased SOM mineralization. Soil texture also impacts CH₄ and N₂O fluxes. Soil structure and texture affect hydrological properties and thus the leaching behavior of soils and the mineralization rate.

Weather patterns

Peak losses of N may occur in early spring and autumn in the Mediterranean environment and lower N losses in summer due to low soil water contents. However, in subtropical and tropical environments, large N losses may also occur in summer. Substantial N₂O emissions may occur in soils after significant rainfall events, snow melts, and also during freeze-thaw or spring-thaw events. Even though the soil temperature may be near 0°C, the N₂O emission in cold soils is caused by microbial activity, and the production of N₂O exceeds its reduction to gaseous N₂ at low temperatures.^[10] The strategic application of dairy effluent during dry summer and autumn can significantly reduce N₂O emissions from grazed pastures, and delaying effluent irrigation after a grazing event can reduce emissions by decreasing the levels of surplus mineral N.

Farm management practices

Management practices also indirectly affect GHG emissions by altering soil temperature and moisture regimes. In the short term, drainage and fertilization accelerate GHG emissions significantly although their long-term effects are likely moderated by C accumulation in the aboveground and belowground biomass.

Drainage. Machinery used for drainage may also affect GHG fluxes by compacting the soil and thereby altering properties such as bulk density, air-filled pore space, and hydraulic conductivity. Drainage increases soil temperature, improves aeration by lowering water table depth, and increases the production of highly decomposable fine roots and exudates, thereby stimulating soil microbial activity and enhancing OM decomposition, which increases CO_2 and N_2O and decreases CH_4 fluxes.^[11] In nutrient-rich peat soils, large fluxes of N_2O occur after drainage when increased O_2 availability stimulates nitrification.^[11] The low fluxes of CH_4 from the drained peatlands may be attributed to decreased methanogenesis and/or increased oxidation of CH_4 by oxidizing microbes in the aerobic part of the peat, with part of the CH_4 oxidized in the aerobic peat layers and converted to atmospheric CO_2 . The effect of drainage may persist and may not decelerate the rate of SOM decomposition for a long time.

Irrigation. It moderates soil water content and reduces soil temperature fluctuations compared to no irrigation, but N fertilization can reduce these parameters compared to no N fertilization by increasing canopy cover and water uptake through increased biomass production. Higher N losses are expected from flood-irrigated pastures.^[7] The addition of, as little as, 5 mm of water to a grass sward can increase N_2O emission rates markedly.^[7]

Mounding. Mounding or raised beds may modify the soil microbial processes and increase both CO_2 and CH_4 fluxes.^[11] Mounding creates three subsites (mounds, hollows, and undisturbed ground) with a different microclimate and OM distribution. Mounds increase soil temperature, decrease soil moisture content, and accentuate OM decomposition. N_2O fluxes may increase in mounded hollows and the top of mounds than in undisturbed grounds, probably because soil moisture conditions, temperature, and N availability favor nitrification and denitrification. The two processes may occur simultaneously at shallow depths and result in the gaseous loss of N_2O and N_2 from the soil mineral N pool.^[11] N_2O consumption may take place in waterlogged conditions when denitrifiers reduce N_2O to N_2 . N_2O fluxes may be reduced in both the mounds and the hollows.^[11]

Fertilization. N fertilization typically has a stimulatory effect on N_2O and CH_4 emissions but a variable effect on CO_2 emissions. The extensive application of N fertilizer also increases leaching of N. Both fertilized and unfertilized soils emit N_2O . While fertilizer N is a source of N_2O in case of fertilized soils, the mineralization of SOM contributes to the production of N_2O from unfertilized soils. Perennial grassland generally maintains higher levels of SOM compared to those rotated cropland.^[12] N_2O escapes from soils especially after the applications of inorganic N fertilizer (e.g., urea and mono-ammonium phosphate) for crops and pastures of mixed farming operations. Unlike crops, most pastures have an active extensive root system throughout the growing season. N_2O emission after the application of anhydrous NH_3 can be 2 to 4 times higher than surface applying urea, ammonium NO_3^- , or broadcasting urea. The surface application of fertilizer and manure is subject to greater volatilization losses than injected fertilizer, predominantly as NH_3 , which is eventually deposited downwind in environments where it may result in N_2O emissions. More than 50% of the fertilizer N can be lost as N_2O through the process of denitrification or nitrification (depending on soil conditions), to produce soluble NO_3^- , which may be removed through leaching and runoff.^[13] Fertilizing with ammonium fertilizers, such as urea, increases the potential for NH_3 emission, but under anaerobic flooded soil, it could minimize gaseous N emissions through denitrification.^[14] Fertilization may stimulate the N-limited decomposing microorganisms. In addition, it also increases the aboveground standing plant biomass, root biomass, which increases rhizospheric deposition and autotrophic respiration. It is the dominant practice affecting GHG emissions in the short term, and its effects appear short lived and of small magnitude. The effect of N fertilizer on increase in CH_4 emissions has been attributed to NH_4^+ ions inhibiting CH_4 oxidation by competitive inhibition of the mono-oxygenase enzyme and also inhibitory effects of N on soil methanotrophs.^[11]

Biotic Factors

Species

In the United States, beef cattle are responsible for the highest proportion of direct N_2O emissions from grazed lands because the vast majority of grazed lands are used for beef production.^[3] In general, emissions from managed grazed land are about twice those of managed manure.^[3] This is due to large numbers of beef cattle on grazing land (more than 80% of all cattle) compared to feedlots, which are a source of managed waste.^[3] The distribution of manure by animals during grazing at the soil surface is uneven; however, distribution can be more uniform with sheep than with cattle grazing.^[15] Grazing sheep and cattle together increases soil bulk density, OM, and grass yields compared with grazing sheep or cattle alone.

Manure

The deposition of animal excreta on pastures, including manure and effluents in grazing lands, results in a patchy distribution of N and C and consequently enhanced biogenic transformations of the nutrients.

Uneven deposition of excretal N by grazing animals can result in hot spots equivalent to an application of 400–2000 kg N ha⁻¹ yr⁻¹ in the small affected area leading to wide spatial and magnitude variations in N₂O emissions. These hot spots correspond to 14.5% ha⁻¹ yr⁻¹, considering a patch area of 0.4 m² per urine deposition.^[16] Emission factor may be different for urine and fecal depositions. Majority of CH₄ comes from feces, and on average 0.96 and 0.03 g CH₄ day⁻¹ cow⁻¹ are emitted from feces and urine, respectively, in grazing cattle,^[17] whereas N₂O emissions are more from the urine, which contains higher concentrations of N and also a more readily available mineral-N form than the feces. The amount of N lost from urine patches depends on the N load deposited, the time of year when urine is applied, and the soil type. N₂O emissions after urine application are higher in soils with high moisture and high temperature. The addition of urine causes the release of SOC by hydrolyzing OM, leading to increased N₂O production when O₂ diffusion is restricted. Cattle urine N concentration is typically 6–7 g N/L when the cattle are grazing pasture while urine-affected, compacted winter forage soils can result in relatively large N₂O fluxes. Winter grazing of *Brassica* crops such as swedes and kale during high soil moisture conditions leads to urine being excreted onto wet, compacted soils, which is likely to result in significant N₂O emissions. N₂O emission factor for cattle urine is 0.20% of the applied urine N in Brazil and 0.66% in the United Kingdom.^[16] Intergovernmental Panel on Climate Change lists a default N₂O emission factor from cattle urine of 2%, i.e., 2% of the urine N is assumed to be emitted as N₂O.^[1] In general, 0.1–3.8% of urine N and 0.1–0.7% of fecal N are emitted to the atmosphere as N₂O.^[16]

Grazing type and intensity

The quantity and form of N lost from grazing lands are mainly a result of grazing intensity, which affects the spatial distribution of urine patches. The intensity and timing of grazing can also influence the growth, C allocation, and plant species of grasslands, thereby affecting the amount of soil C. Increased soil C on optimally grazed lands is often greater than on ungrazed or overgrazed lands. Overgrazing and continuous trampling decrease the efficiency and viability of the pasture systems. There is a significant difference in CH₄ emission rates depending on whether pastures are rotationally or permanently grazed, and a 9% lower CH₄ production ha⁻¹ day⁻¹ was measured in rotationally grazed pastures compared to continuous grazing.^[18] Furthermore, the use of pasture diminishes emissions from manure storage (because there is less

manure in storage systems) but increases N₂O emissions from deposition by grazing animals.

Rangelands

Although the rates of N₂O emissions from most rangelands may be low, considering the extent of total rangeland area, it is important to measure N₂O emissions in the field over an extended period, as small amount of rainfall may trigger significant nitrification activity and hence N₂O production following a prolonged dry period. The N₂O emissions from the urine patches may be significant in rangelands. Usually animal feces are voided in large areas, thus avoiding anaerobic N mineralization from animal waste.^[7] In extensive grazing system, large areas of rangelands are used for grazing purpose. In view of increasing the pasture availability, tree clearing is commonly practiced that may result in increased soluble C even in deeper layers of the rangelands.^[7] These are associated with CO₂ concentration due to microbial respiration and hence intense O₂ demand, resulting in partial anaerobiosis.

Leguminous pastures

In intensive grazing system, most of the N₂ supply for dairy pastures is derived from pasture legumes, which are typically seeded in heavily grazed pastures. Forage legumes on grazed lands contribute to N₂O emissions, because legumes fix N₂ from the atmosphere into forms that can be used by plants and soil microbes, N₂ can become mineralized in the soil and contribute to nitrification and denitrification. Thus, more N₂ added to soil yields more N₂O released to the atmosphere. N₂O emissions from legume-based pastures may be in the order of 1–2 kg N ha⁻¹.^[7] There is a greater N₂O emission with legumes than with non legumes due to the presence of rhizobium bacteria related to root nodules. Because of lower C/N ratio and higher N concentration, legumes decompose rapidly compared to non legumes, thereby increasing N₂O emissions.^[15]

Burning of savannas

In tropical savannas, where fire is frequently used as a pasture management tool, the N₂O and NO production rates are much higher. In such a system, where N is mineralized rapidly after fire, N₂O emission rate could be higher, especially if fire is followed by moderate rainfall events.^[7] GHG emissions can be significantly reduced following a savanna fire early in the dry season because the moisture content of plant material is still relatively high resulting in low-intensity fires that can reduce fuel loads without killing trees.^[19]

MITIGATION STRATEGIES

A mitigation practice may affect more than one gas, by more than one mechanism, e.g., strategies intended to

sequester C in soils may impact the fluxes of N_2O and CH_4 .^[3] Furthermore, the temporal pattern of influence may vary among practices or among gases for a specified practice. One strategy that may be feasible for more intensely managed pastures is the use of nitrification inhibitors (NIs).

Nitrification Inhibitors

The application of NI to the soil can minimize N_2O emission by 30–80%.^[20] NI can reduce NO_3^- leaching and also promote better N utilization in the soil. It temporarily delays the bacterial oxidation of NH_4^+ to NO_2^- by inhibiting *Nitrosomonas* spp. bacteria.^[16] An ideal NI should specifically block NH_4^+ oxidation to NO_2^- but not NO_2^- oxidation to NO_3^- . However, a NI does not inhibit nitrification indefinitely, and its effect depends on its rate of degradation and persistence in soils. Examples of NI are dicyandiamide, piadin, acetylene, nitrapyrin (2-chloro-6-(trichloromethyl)-pyridine), and 3,4-dimethylpyrazole phosphate. However, it is difficult to apply NI on commercial pastoral farms because there is no technology available to precisely apply only on urine patches and the application over the whole farm is not economically efficient.^[16]

Biochar/Agrichar

It is a promising technology to boost the SOC besides producing bioenergy. The process involves pyrolysis of forest or agricultural biomass to form a charcoal product known as biochar. Under proper conditions, 30–50% of the biomass C is retained in the porous biochar structure. The biochar is highly recalcitrant in soils and can sequester C for thousands of years. The application of biochar also reduces N_2O emissions from urine patches.^[12]

Grazing Management Practices

Grazing intensity

Any practice that increases the photosynthetic input of C or slows the return of stored C through respiration will increase stored C, thereby enhancing SOC or building C sinks.^[14] So, light grazing should be practiced instead of heavy grazing. Optimal grazing management can enhance the accrual of soil C.

Controlled grazing

Grazing management may affect N_2O emissions from pasture, e.g., in Inner Mongolia, increasing stocking rates of sheep reduced N_2O emissions compared with those from ungrazed pasture. Reducing the sheep stock number and spring lamb production appears to be an option for reducing N_2O emissions from Australian grazing lands.^[7] Increasing the number of grazing animals and grazing in the late

fall/winter and in the early spring will ensure that the manure will be spread over the field. Another method of grazing called swath grazing may also be followed. This practice spreads manure around the field and will also decrease the feeding costs.

Rotational grazing

Grassland practices such as rotational grazing can reduce C losses and promote C sequestration in grazing lands.^[3] By subdividing pastures and rotating cattle, producers can manage stocking densities and grazing duration to allow the vegetation time for rest and recovery.

Soil Conservation Practices

These practices may sequester soil C and enhance CH_4 consumption. The largest potential is decreasing soil erosion and restoring eroded and degraded soils, so that they become net C sinks. Grassland systems that have been degraded in the past or maintained under suboptimal management conditions are most conducive to sequestering additional C. Soils that have been historically cropped using conventional tillage are often depleted of C because tillage disturbs soil aggregation and warms soil, whereas both increase decomposition rates. C-depleted soils can act as CO_2 sinks upon conversion to grazing because grazed soils are typically not ploughed. Although grazed mineral soils are a net sink of CO_2 , grazed organic soils are a net source. If half of the grazed organic soils were converted back to wetlands, CO_2 emissions from this source could be reduced from approximately 4.6–2.3 Tg $\text{CO}_2\text{e yr}^{-1}$.^[3]

CONCLUSION

The production of GHGs from grazing land is sporadic in both time and space, and so it is a challenge to scale up the measurements of GHG emissions from a given location and time to regional and national levels. The exact approaches also depend on local conditions and, therefore, vary from region to region. A national management strategy is needed to reflect region-specific soil types and climatic conditions. Regionally appropriate conservation agricultural practices should be identified to build up SOM, promote SOC, and mitigate GHG emissions. However, there is large uncertainty in the emission factor, and different countries and regions must have different specific gaseous emission factors due to different soil, temperature, rainfall, and grazing systems. It is also difficult to obtain definitive gas flux values because of the analytical techniques, large spatial variability, and seasonal variability. Simulation modeling should complement these measurements over seasons and locations.

FUTURE PERSPECTIVES

Although GHG emissions derived from soil have been researched for 50–60 years, there are geographic regions and grazing land systems that have not been well characterized. Forage quality should be improved for grazing animals on smaller livestock operations through better pasture management. The effectiveness of NI should be assessed under different conditions and for different soil types. Additional incentives and educational programs are needed for land managers to adopt improved grazing management. More research is needed on the potential use of biochar to reduce GHG emissions from grazing systems. Improved methodologies should be developed to improve the accuracy of determining changes in SOC and GHG emissions from grazing lands. Comprehensive research program along with a whole system analysis is needed to account for the interactions to arrive at cost-effective and efficient GHG mitigation management, policy, and legislation options for sustainable management of grazing lands.

Abstract

Major challenges in sustainable land use ecosystems have emerged since the 1980s in the China's North Eastern Plain (CNEP) because of increased competition for land, groundwater, labor, and other natural resources driven by growing food demand, urbanization, and industrialization. Food security has been ensured at the cost of weakening or loss of other land use ecosystem functions and services such as carbon (C) sequestration, groundwater purification, land use diversity, local tradition and land use knowledge, open space, and so on. Land expansion and land use intensification have led to high rates of nitrogen (N), phosphorus (P), and potassium (K) use since the 1960s averaging 1.66, 4.43, and 1.46 times the national average rates for China, respectively. Further, intensive irrigation has caused rapid groundwater depletion. Consequently, CNEP is China's bread basket accounting for almost 35% of maize (*Zea mays*) and 70% of wheat (*Triticum aestivum*) production. For achieving sustainable land use systems and restoring multi-function services, a series of green revolutions must be realized. These green revolutions must limit the conversion of natural land into managed land use systems, restrict the urban encroachment, restore soil quality of intensively used soils, map the permanent prime land and ecological hot spots, and narrow the yield gap on arable land. Living Common Community Management Units (LCCMUs) including arable land, wetland, forest land, grass land, and traditional land use and cropping knowledge should be built through an integrated application of top-down method but with the bottom-up approach. Closing potential productivity gap while reducing resources-intensive use should be ensured by improved arable land quality management based on the LCCMU. Sustainable intensification including agronomic yield, with due consideration of spatial and temporal variability at a regional level, can be achieved by application of precision agricultural technology and investment policy in rural land.

CHALLENGES

China's North Eastern Plain (CNEP) is an important food-producing region. It involves the double-cropping system of winter wheat (*Triticum aestivum*) and summer maize (*Zea mays*). The CNEP produces 35% of China's maize and 70% of wheat. The average yield of grain crops (kg ha^{-1}) has increased from 1582 to 5860 for wheat and 4492 to 5610 for maize between 1985 and 2010.^[1] The yields are 1.25 and 1.07 times those of China's national average yields of wheat and maize, respectively. However, CNEP accounts for about 16% of China's arable land but has access to only 7.6% of China's renewable water resources compared with the highly endowed southern plains. Therefore, the dramatic increase in crop yields and production in the CNEP has been achieved by the expansion of arable land, intensive irrigation, and high rates of nitrogen (N), phosphorus (P), and potassium (K) use since

1960 averaging 1.66, 4.43, and 1.46 times those of the national average rates, respectively. The conversion of arable land to built-up land and of natural ecosystems to arable land, as well as the intensive use of chemical fertilizers, has made CNEP a major source of greenhouse gases (GHGs). On the other hand, the utilization of approximately 900 mm of water for annual production of wheat and maize^[2] has caused severe groundwater depletion. Both west–east and south–north transects chosen to conduct the buffer analysis reveal the existence of four large cones of shallow groundwater depression in Mancheng ($\sim 1.50 \text{ m yr}^{-1}$), Shijiazhuang ($\sim 2.00 \text{ m yr}^{-1}$), Xingtai ($\sim 1.75 \text{ m yr}^{-1}$) in Hebei Province, and Anyang ($\sim 1.25 \text{ m yr}^{-1}$) in Henan Province. Further, three large cones of deep groundwater depression also exist in Shijiazhuang ($\sim 2.25 \text{ m yr}^{-1}$) and Hengshui ($\sim 2.00 \text{ m yr}^{-1}$) in Hebei Province and Dezhou ($\sim 3.00 \text{ m yr}^{-1}$) in Shandong Province.

There is unknown solution to sustainable land use ecosystems, except through the realization of soil-based green revolutions in this region. There exists high competition driven by land, water, labor, energy, and other natural resources for continuous increase in food demand, rapid urbanization and industrialization, and multifunction services by local communities. Thus, soil-based green revolutions are needed to increase crop production from available cultivated land in ways that do not jeopardize the environment nor undermine the productive capacity of land and water resources.

DECREASE IN ECOSYSTEMS MULTIFUNCTION AND SERVICES SINCE THE 1980S

The land ecosystems provide essential ecosystem functions and services such as the net primary productivity (NPP), renewal of freshwater, regulation of climate and biogeochemical cycles, maintenance of soil fertility, preservation of habitat for biological diversity, and well-being of household (Fig. 1). However, it is the continuous increase in agricultural intensification since the 1980s that has advanced crop production quickly and has transferred the historic grain production over centuries from the south to the north. Unfortunately, agricultural intensification in conjunction with the high rate of application of chemical fertilizers and the irrigation from groundwater have created the vicious cycle of higher wheat yields, more water depletion, and more severe deficit of groundwater.

Simultaneously, the continuous conversion of natural land systems (wetlands, coastal deposits, grass lands, etc.) to arable land for growing crops and arable land to build-up land for city, rural settlements, and factories have greatly altered ecosystem functions and services. The loss of natural ecosystems has exacerbated GHG emissions, decreased land use and crop biodiversity, reduced surface water, and increased outward migration of rural households.

Both arable land expansion and agricultural intensification have advanced crop production. However, the land ecosystem multifunctions have been weakened, destroyed, or lost at an accelerated rate. Thus, the land ecosystem functions and services should be restored into land use zoning on the basis of the spatial land ecosystem services. The marginal arable land converted from the natural ecosystems should be restored, prime farmland should be marked permanent, and urban encroachment should be zoned. The comprehensive and multifunction services should be rehabilitated by means of top-down method, but with the bottom-up approach based on Living Common Community Management Unit (LCCMU) of arable lands, wetlands, forest lands, grass lands, traditional lands, and cropping knowledge. The strategy is to close the arable land potential productivity gap and reduce input of chemical fertilizers. The goal is to improve arable land quality through sustainable intensification of agroecosystems.

THE WAY FORWARD

Restoration of Land Ecosystems Multifunction Services

There is a trilemma of food security, ecosystems multifunctions, and city development in the CNEP (Fig. 2). The city growth boundary, the permanent prime farmland, and the ecological hotspot must be zoned through the strategy of preserving land ecosystem multifunctions and services.

Restore Excessive Marginal Arable Land Expansion

Sustaining land ecosystem multifunctions and services must be a high priority. Natural ecosystems (e.g., rivers, ponds, grasslands, wetlands, and other natural land use systems) were in abundance prior to the 1980s, which

Fig. 1 Conceptual framework for intensifying land use and ecosystem multifunction in the China north plains. The provisioning of multifunction under different land use regimes can be illustrated with these diagrams, in which the condition of each ecosystem service is indicated along each axis. For purposes of illustration, we compare two hypothetical landscapes: an excessive intensively land use system (left) and a sustainable intensively land use system (right). The intensively managed land use system, however, is able to produce high crop production at the cost of diminishing other land use multifunction. Multifunction should be restored (right).

Fig. 2 Concept framework for trilemma for food security in China north eastern plains. Grand challenges between food security, ecosystem multifunction, and urban growth are to be solved within the highest densely populated and scarce land resources in China. The urban growth boundary, the permanent prime farmland, and the ecological redline should be zoned by introduction the ecosystem multifunction.

strengthened the ecological network. However, the continuous expansion of arable land has strongly altered the land use and land cover. Thus, there is a strong need to restore ecosystem multifunctions and services network, which must be zoned and built.

Groundwater has been severely depleted in the CNEP plains by intensive land use, especially in the northern plains, which has not only led to irreversible and adverse ecological effects but has also exacerbated water scarcity for 430 million people. Thus, sustainable use of groundwater is essential, which must be protected in several critical regions (e.g., Hengshui and Cangzhou), and not used for irrigation of vegetables and winter wheat.

Mapping Permanent Prime Cultivated Land Zone

The CNEP has experienced a rapid urbanization since the 1980s. Consequently, large tracts of arable lands have been converted into built-up land, especially around the capital of Beijing and other provincial capitals in the region. The loss of high-quality arable land is the driving force leading to conversion of natural ecosystems to arable land and agricultural intensification.

Appropriation of an adequate amount of area to the arable land use in the region is necessary to advance food security and economic development. Thus, prime arable land must be protected around large cities (e.g., Beijing, Tianjin, Shijiazhuang, and Tanshan).

The permanent farmland zone should include not only cultivated lands but also forest lands, grass lands, wetlands, and village settlements. The main function for the permanent farmland zone is to enable households to achieve diverse land use patterns, grow diverse crops, advance food security, and generate income by growing some cash crops. In this zone, land should be reallocated according to tenure rights and property ownership to improve production

efficiency. Urban encroachment must be prohibited on prime farmland of a high quality.

Mapping the City Growth Boundary

The local government provides incentives to convert arable land into built-up land because of the high return from city encroachment and factory production. However, the city sprawl has led to severe and negative environmental effects.^[3] The concentration of transportation and industry in urban centers has exacerbated the point sources of carbon dioxide and other GHGs, which affected the region's climate. In addition, several trace gases (e.g., nitric oxide, nitrogen dioxide, ozone, sulfur dioxide, and nitric acid), and some organic acids, and urban environments have altered the energy budget leading to the formation of urban heat island (UHI) effects. These UHI effects not only affect local and regional climate but also pollute water resources and air quality, jeopardize human health, and adversely impact biodiversity and ecosystem functioning.

Therefore, smart growth city should be the future priority strategy. An innovative strategy of urbanization proposed by the central government must focus on the effective use of the already built-up land in both urban and rural centers and ban any new urban encroachment in the region. Thus, city growth boundary should be mapped based on the arable land quantity and quality, groundwater depletion, and land ecosystem functions and services.

Restore Local LCCMU

The comprehensive and integrated LCCMU system should be restored within the CNEP on the basis of the top-down method but with a bottom-up approach (Fig. 3). The top-down method fully considers the change of food security, land demand, agricultural development, rural household

Fig. 3 Concept of the land rehabilitation for multifunction on the basis of the merge of top-down method and bottom-up approach.

shift, infrastructure, and road development plans at the macro level.

However, there are a lot of farmers who live in the rural villages. They have the similar traditional ecosystem knowledge, traditional land use practices from similar soil quality, groundwater distribution, and climate. Thus, traditional land use knowledge should be introduced into the LCCMU on the basis of the bottom-up approach.

Indigenous peoples' knowledge of ecosystems usually results in diverse agricultural landscapes managed for multiple uses, resulting in local food self-sufficiency and ecosystem multifunctions.^[4] Traditional methods are particularly instructive because they provide a long-term perspective on successful land use management. Traditional agroecosystems and associated land diversity are the results of a complex coevolutionary process between natural and social systems, resulting in strategies for ecosystem appropriation.

Thus, a few key principles seem to underlie the sustainability of LCCMU systems—the land use diversity, the soil organic matter (SOM) accumulation, the enhanced recycling of biomass and nutrients, the minimization of resource losses through soil cover and water harvesting, and the maintenance of high levels of functional biodiversity.

Close the Arable Land Potential Productivity Gap

Understanding the arable land potential productivity gap for each plot of arable land (Fig. 4) based on the crop biophysical limits, and possibility of attainable maximum crop yield is critical. The realization of the potential productivity gap is a high priority for research, investment, and policy intervention.

Raise Yield to the Crop Biophysical Limits in Different Climate–Soil–Groundwater Zones

China comprises 12 agroecological zones, 49 agroecological subzones, and 105 agroecological regions.^[5] However, drastic changes have and are occurring in climate, soil quality, groundwater, dominant crops, and cropping

Fig. 4 Concept model for increase ceiling of crop yield potential productivity and sustainable closing productivity gap while reducing input by improved arable land quality management. (A) The scenario of maximum attainable crop yield by household with current managed soil-crop practices upon the improved arable land quality. (B) The scenario of maximum crop yield with existing technology of soil-crop management upon improved arable land quality. (C) The scenario of crop yield with the existing crop varieties upon improved arable land quality. (In) The scenario of input by household for crop yield upon improved arable land quality management.

systems. Thus, new and emerging agroecological zones should be rezoned on the basis of some limiting factors and land's capacity to produce goods and services. Improving yield potential of crop varieties through advancement in crop breeding technology will be a critical component for future crop production.^[6] However, crop productivity depends on continued innovations to control weeds, diseases, insects, and other pests as they evolve resistance to different control measures, or as new species emerge, or are dispersed into new regions. Thus, continued efforts are needed to raise the productivity and crop yield to biophysical limits.

Attaining Yields to the Biophysical Limits by Introduction of Improved Crop–Soil Management

Whether the highest yield can be attained depends on the improvements in crop–soil management and the corresponding arable land quality. Improvements in attainable crop yields to the climate–soil limits can be realized by precision management of crop–soil system while reducing GHG emissions. An “integrated soil–crop systems of management for maize” has been introduced in China.^[7] This involves the use of the hybrid-maize simulation model to maximize the use of solar radiation and the exploitation of temperature changes. It also uses a root-zone, in-season N management strategy to synchronize the supply of N from soil and fertilizer and with crop demand.^[8] The experimental success has provided the data basis on crop biophysical limits for the specific agroecosystem zone, but important issues to be addressed include scaling up of agroecological approaches for improving success in the experimental sites of the region.

Advancing the Maximum Attainable Yield in Different Regions by Improving Arable Land Quality

A high quality of soil under arable land use in the United States supports high crop yield even with less input. On the contrary, high crop production in the CNEP region has been realized by higher input because of low inherent soil quality. Consequently, farmers in the CNEP region have to apply high rates of N, P, and K to obtain high yields. Therefore, the production system in the CNEP is not sustainable. Strategically, the maximum attainable yield in different regions must be realized by improving soil quality of arable land use (Fig. 4). High crop yields to the upper limits could be realized by restoring soil quality^[9] and improving convenient infrastructure (e.g., rural roads, irrigation, and drainage systems). The goal is to reduce inputs of chemical fertilizers, water, labor, and so on by reducing losses and improving use efficiency. Innovative strategies include improvements in irrigation and drainage systems, field leveling, and improving rural roads linking the field to village and market.

Furthermore, improvement in soil quality involves increasing SOM content,^[10] improving structure and tilth, and reducing salinity and sodicity. In addition, adoption of best management practices (BMPs) (e.g., Northern Territory farming, integrated nutrients management (INM) with combined use of organic manure and balanced fertilizer, organic manure, improved grazing, and harvesting) is necessary to improving SOM contents.

Realizing the Maximum Attainable Crop Yields by Providing Subsidy Incentive and Prompting Rural Development

There are several options available to help farmers realize the maximum attainable crop yield in different agroecosystem zones through improvement of the deteriorated or non-existent rural infrastructure.

Investments in rural roads can increase land production by intensifying land use, as well as consolidating the links between agricultural and non-agricultural activities within rural areas and between rural and urban communities.^[11]

Investments are also needed for developing new water management infrastructure. While the economic cost of irrigation may be unprofitable, productivity can be enhanced by soil–water conservation, by increasing efficiency of the systems, and by increasing crop productivity per unit of water used. Among strategies of building, the crop yield is the need for a collective action at the local level, as well as the participation of government and non-governmental organizations at the community level.

Sustainable Intensification

One of the biggest opportunities for restoration of land use multifunctions and services is the development and implementation of a new pattern of sustainable of agriculture.^[12] This new pattern should be based on the combination of local traditional knowledge and the modern agricultural managements.

Local rural farmers use a wide range of techniques that are knowledge intensive rather than input intensive. Traditional knowledge constitutes intercropping, SOM management, enhanced recycling of biomass and nutrients, minimization of resource losses through soil cover and water harvesting, and maintenance of high levels of functional biodiversity. Traditional agriculture is a critical source of genetic material and regenerative farming techniques.

Indeed, traditional knowledge is the foundation of a sustainable intensification of managed rural land and is critical to introducing agricultural modernization among resource-poor farmers. The latter may include prudential use of monocultures, new varieties, agrochemical packages, all of which are critical to increasing yields, labor

efficiency, and farmers' income. The foundation of sustainable intensification must be grounded in traditional knowledge for site-specific situation.

Therefore, sustainable intensification could succeed in the context of combining the traditional and modern agriculture, which can meet the growing demands of crop production for food, conservation, and enhancement of soil C stocks. Sustainable intensification opportunities exist in three key areas:

1. *Yield intensification* implies the increase in crop production per unit area and inputs. It begins with closing the yield gap at the regional level and refers to the yield difference between lower yielding production systems and the highest yields that can be achieved with BMPs for similar climate–soil conditions.
2. *Temporal intensification* implies an increase in the number of different crops grown per year, through local and traditional crop diversification including crops for food, and green manure for improving soil quality.
3. *Spatial intensification* implies land optimization and the implementation of MBPs for addressing trade-off among multiple competing land uses on the basis of soil quality, groundwater, and traditional cropping systems. It requires an integrated and comprehensive approach to managing land systems covering all production and conservation uses.

In general, CNEP is the important food production region of China. It is the continuous increase in agricultural intensification since the 1980s, which has transferred the historic grain production over centuries from the south to the north. However, agricultural intensification related to high rate of application of chemical fertilizers and the irrigation from groundwater have created the vicious cycle of higher wheat yields, more water depletion, and more severe deficit of groundwater. The regional consequences of arable land expansion and the excessive intensification have led to severe loss of land ecosystem functions and services. There is no silver bullet to sustainable land use, along with realization of the soil-based green revolutions in this region. Addressing the following challenges requires action through green revolutions in the CNEP plains: (a) restoration of the land use ecosystem multifunction services should be a high priority; (b) crop production should be continuously increased; and (c) shift of the unsustainable intensification to green intensification should be the logical way to solve the dilemma of increasing crop production, restoring groundwater depletion, and reducing the GHG emissions.

Greenhouse Effect

Rattan Lal

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

World soils constitute a major terrestrial carbon (C) pool, and even a small change in the C pool of world soils can lead to a substantial change in the atmospheric C pool. A considerable increase in the atmospheric C pool, since the industrial revolution, has come from the soil and biotic pools. Agricultural activities that lead to emissions of carbon dioxide and methane from soil to the atmosphere include deforestation, biomass burning, and plowing. Gaseous emissions are accentuated by soil degradative processes. Conversion to an appropriate land use and adoption of judicious management can reverse the trend by making world soils a major sink for C. The soil organic carbon content of cropland soils can be maintained or enhanced by use of conservation tillage, application of crop residue mulch, and judicious use of chemical fertilizers and organic amendments that enhance soil quality.

INTRODUCTION

Earth's vast reservoir of carbon (C) is contained in four distinct pools (Table 1). The soil C pool comprises both organic and inorganic forms. Soil organic carbon (SOC) is estimated at 1550 Pg (1 Pg = petagram = 10^{15} g = 1 billion metric tons) and soil inorganic carbon (SIC) at 950 Pg. The atmospheric pool contains 760 Pg of C, and the vegetation for the biotic pool amounts to about 610 Pg of C. The pedologic or soil C pool, with a total reserve of about 2500 Pg in both organic and inorganic form, is about 3.3 times the atmospheric pool and 4.1 times the biotic pool.^[1–10]

In addition to being a pool, world soils also play a major role in the global C cycle (Fig. 1). The SOC pool is highly dynamic, concentrated near the soil surface, and comprises material of plant and animal origin at various stages of decay and decomposition. A large part of the SOC pool is held in the organic soils of tundra and boreal forest ecosystems. It is the dynamic SOC pool that is intimately connected with the projected global warming or the accelerated greenhouse effect. Change in soil C pool by 1 Pg is equivalent to 0.47 ppm change in atmospheric concentration of carbon dioxide (CO₂).

These global pools are interconnected through fluxes of C (Fig. 1). The atmospheric pool has been increasing at the expense of other pools. Some known sources and sinks are listed in Table 2. The two principal sources are fossil-fuel combustion (6.8 Pg/yr) and deforestation and soil disturbance (1.6 Pg/yr). The two proven sinks are atmosphere (3.5 Pg/yr) and ocean (2.0 Pg/yr). The unknown sink for the remaining 2.7 Pg/yr is most likely the world soils and other terrestrial ecosystems.^[11] The exchanges occur between: 1) world biota and the atmosphere with an annual flux of 120 Pg photosynthesized by plants and

returned to the atmosphere in equal amounts through plant and soil respiration and 2) oceans and the atmosphere amounting to an annual flux of 107 Pg from atmosphere to the ocean and return of 105 Pg making the ocean a net sink of about 2 Pg/yr.

There has been a steady increase in the atmospheric concentration of greenhouse gases [GHGs, CO₂, methane (CH₄), and nitrous oxide (N₂O)] since the beginning of agriculture,^[12] but more strongly with the onset of the industrial revolution in the 1850s. This increase is primarily due to human activities, e.g., industry-based fossil-fuel consumption, and agriculture-based deforestation and conversion to cultivable land involving intensive use of fertilizers and manures. The CO₂ concentration in the atmosphere has increased from 280 ppmv in the 1850s to about 370 ppmv in 2000^[4] and is increasing at the rate of 0.5% per year (Table 2).

AGRICULTURAL ACTIVITIES AND GHG EMISSIONS

GHGs are emitted by numerous agricultural activities (Fig. 2). Agricultural sources of CO₂ are deforestation, land use conversion, biomass burning, soil plowing and other mechanical disturbances of the topsoil, and fossil-fuel consumption. About 50% of the total increase in atmospheric CO₂ is attributed to agricultural activities. Among principal sources of CH₄ are enteric fermentation in ruminant animals, cultivation of rice paddies, anaerobiosis in poorly drained soils, and biomass burning. Use of nitrogenous fertilizers and manures is the principal source of N₂O emission. Soil management plays a major role in the type and amount of emission of GHGs.

SIC	950
Vegetation	610
Atmosphere	760

Source: From Kennel.^[4]

The rate of oxidation or mineralization of the SOC pool depends on its composition and numerous other factors. Factors that increase oxidation are soil disturbance, high soil temperature, lack of protective vegetal cover, and risks of soil erosion and degradation. In contrast, factors that decrease oxidation are minimal soil disturbance, low soil temperature, minimal soil disturbance, presence of protective vegetal cover, and high soil resilience. The annual flux of CO₂ from soil to the atmosphere, about 60 Pg, is due to soil respiration and its rate increases with increase in soil temperature. The mean resident time of SOC in soil is about 32 years, but some resistance humic substances can stay in soil for thousands of years. Losses of SOC pool by oxidation are accentuated by soil erosion of water and wind^[13–15] and other degradative processes.

Introduction of mechanized agriculture (e.g., tractor based plowing and other farm operations causing soil disturbance) have accentuated losses of SOC pool from cultivated soils. Some soils lose as much as 25% of their SOC pool within 1 year after deforestation and cultivation.^[16] The rate of loss of SOC content is more in the tropics than in the temperate climate. Some tropical soils, cultivated for millennia in Asia, have extremely low levels of remaining SOC content (as low as 0.2%). These soils have probably lost 75–80% of their initial SOC content. It is likely that as much as 66–90 Pg of C in the atmospheric pool has been contributed by world soils.^[17]

In addition to being a source of atmospheric C (as CO₂, CH₄, or CO), world soils are also a major source of N₂O. The relative contribution of N₂O has also increased because of the intensive use of nitrogenous fertilizers since World War II. The magnitude of N₂O emission varies among soils, type of nitrogenous fertilizer used (formulation), climate, land use, and soil and crop management.^[3]

POTENTIAL OF WORLD SOILS AS C SINK

The SOC in most agricultural soils is below their potential capacity. As a considerable part of atmospheric CO₂ has come from world soils, it is possible to reverse the trend and store C back into the soil. Increase in SOC content, through change in land use and farming practices, could slow the rate of increase of atmospheric CO₂ and provide a negative feedback to the greenhouse effect. Because of their vast pool, it is very likely that world soils are the unknown sink for 2.7 Pg of C/yr (Table 2).

Principal mechanisms by which soils can be used as an effective sink for some of the atmospheric CO₂ through

Fig. 1 Interactive effects among the three C pools (soils, biota, and atmosphere) have led to a steady increase in the atmospheric pool at the expense of the soil and biotic pools. Values in the arrow indicate direction and magnitude of the known fluxes, while the question mark indicates the lack of information.

increase in SOC content include: 1) humification or conversion of biomass into resistant humic substances with long turnover time; 2) aggregation or formation of stable organo-mineral complexes that render SOC inaccessible to microbes; and 3) deep incorporation of SOC below the plow layer through deep root system development and translocation by leaching. These mechanisms can be set-in-motion through adoption of proper land use, choice of appropriate farming/cropping systems, and use of judicious soil and crop management practices.^[18–22]

The potential of C sequestration in world soils depends on the land use, present level of SOC content, the initial SOC content prior to soil disturbance by deforestation and conversion to other land uses, climatic or eco-regional characteristics, and farming systems. Among all land uses, the largest potential increase in SOC content is in arable lands. If the SOC content of the world's arable land can be increased at the low rate of 0.01% per year to 1 m depth, which may be difficult to achieve for soils of arid and semiarid regions, the C sequestration potential of such a possibility is about 2 Pg/yr (Eq. 1). These calculations are based on the assumption that the mean bulk density of soils is 1.33 Mg/m³.

C sequestration potential of 1500 × 10⁶ ha of world arable land

$$= (1500 \times 10^6 \text{ ha})(10^4 \text{ m}^2/\text{ha})(1 \text{ m}) \times (1.33 \text{ Mg/m}^3)(1 \times 10^{-4}/\text{yr}) = 2 \text{ Pg/yr} \quad (1)$$

MANAGING WORLD SOILS FOR MITIGATION OF THE GREENHOUSE EFFECT

There are several soil management practices that can be used to increase SOC content and reduce the risk of accelerated greenhouse effect (Fig. 3). These practices can be grouped under two broad categories: 1) those

Fig. 2 Agricultural activities and emission of GHG from soil to the atmosphere.

that decrease losses due to soil degradative processes and 2) those that increase SOC content through soil restorative processes (Table 3). Principal strategy is of agricultural intensification through adoption of appropriate land use and recommended agricultural practices.

A tremendous potential of mitigation of the greenhouse effect exists through restoration of degraded and drastically disturbed soils. It is estimated that the area of the degraded soils of the world is about 2.0 billion hectares.^[23] These soils include the cultivated land area, pastoral land areas, and other managed and natural ecosystems. Restoration to improve soil quality can lead to an increase in ground biomass production (both above and below the ground), increase in SOC content, and strengthening of a negative feedback to the greenhouse effect. The C sequestration potential of restoration of degraded soils is about 3 Pg/yr (Eq. 2):

$$\begin{aligned} \text{C sequestration potential of restoration of degraded} \\ \text{soils} &= (2 \times 10^9 \text{ ha}) \times (10^4 \text{ m}^2/\text{ha}) \times (1\text{m})(1.5\text{Mg}/\text{m}^3) \\ &\quad \times (10^{-4}/\text{yr}) = 3 \text{ Pg/yr} \end{aligned} \quad (2)$$

These calculations are based on the assumption that mean soil bulk density to 1 m depth is 1.5 Mg/m³. The potential of

Table 3 Strategies for increasing SOC content for mitigation of the greenhouse effect.

Practices that decrease loss of SOC content	Practices that enhance SOC content
Soil erosion control techniques	Improved soil fertility and integrated nutrient management
Conservation tillage	Precision farming
Residue management	Nutrient cycling
Terraces and contour barriers	Application of biosolids and biological nitrogen fixation
Improved cropping systems	Restoration of degraded soils
Afforestation	Eroded soils
Decreasing losses of dissolved organic carbon through leaching	Mineland and drastically disturbed soils
	Salt-affected soils
	Water table management (drainage and subirrigation)

3 Pg/yr is almost equivalent to the rate of annual increase in atmospheric C at 3.5 Pg/yr (Table 2) and can be realized over 25–50 years. Realization of this potential requires development of strict land care ethics and global soil policy that must be strictly adhered to. While attempts at decreasing the emissions due to fossil-fuel combustion must be

Fig. 3 Agricultural activities with a potential of sequester C in world soils that decrease the risks of the greenhouse effect.

continued, it is important that the vast potential of world soils in C sequestration is realizable through adoption of known and proven technologies. The attainable potential of world soils for C sequestration is 0.6–1.2 Pg C/yr.^[19]

CONCLUSION

World soils constitute a major terrestrial C pool, and even a small change in the C pool of world soils can lead to a substantial change in the atmospheric C pool. A considerable increase in the atmospheric C pool, since the industrial revolution, has come from the soil and biotic pools. Agricultural activities that lead to emissions of CO₂ and CH₄ from soil to the atmosphere include deforestation, biomass burning, and plowing. Gaseous emissions are accentuated by soil degradative processes including accelerated erosion, structural decline, etc.

Conversion to an appropriate land use and adoption of judicious management can reverse the trend by making world soils a major sink for C. The SOC content of cropland soils can be maintained or enhanced by use of conservation tillage, application of crop residue mulch, and judicious use of chemical fertilizers and organic amendments that enhance soil quality. Restoration of the world's degraded soils and desertification control has a potential to sequester C at the rate of 3.0 Pg/yr.

Abstract

The use of growing media, as opposed to soil *in situ*, has become widespread especially for the production of high-value greenhouse crops as well as in plant propagation and the production of plants in small containers. Growing media provide a root environment that is free of plant pathogens and can have physical and chemical properties that ensure adequate aeration for the root system and optimize the supply of water and nutrients to the shoot. The result is the reliable production of high-quality plant material and the achievement of increased yields compared with conventional soil culture. A wide range of inorganic and organic materials are used as components of growing media. Peat moss has been the most important material in many countries. There is increased interest in the use of organic waste materials such as composted crop residues and biowaste and in the forms of charcoal such as biochar. Systems based on inorganic materials such as rock wool, perlite, and polyurethane foam have been developed in combination with fertigation systems to successfully produce many crops. Standard methods for measurement of the physical, chemical, and biological properties of these materials have been developed and are widely used in the analysis of growing media. Given their success and the need to develop intensive crop production systems, it seems likely that the use of growing media will continue to expand.

INTRODUCTION

The effort to develop growing media on a scientific basis began with the work of Lawrence and Newell at the John Innes Horticultural Institution in the United Kingdom in the 1930s. They developed media based on the use of loam, peat, and sand with added fertilizers. In the 1950s, Baker at the University of California (UC) developed the UC loamless composts based on mixes of peat and sand, as suitable loam was difficult to obtain. Puustjarvi, in Finland, subsequently developed growing media based exclusively on peat. In many countries, especially in Europe, over a number of decades, growing media were based almost exclusively on peat in the 1970s. Fears about the sustainability of the continued use of peat have led to increased interest in alternative materials and a wide range of inorganic and organic, particularly, waste materials are being used as growing media or as components of growing media.

Growing media have been used traditionally mostly for plant propagation, bedding, and pot plant production, but this range of use has expanded to include the total production of many food and ornamental crops especially high-value ones grown under protection in greenhouses. These systems are called soilless culture systems. *Culture: Soil-less* is presented in another separate entry (p. 533).

Because the plants are grown in much restricted volume compared with soil *in situ*, the requirements for the properties of the growing medium, i.e., physical, chemical, and biological, become more stringent.

PHYSICAL PROPERTIES

Because of a broad range of applications much different from growing conditions in agricultural fields, the range of values for physical properties of organic media are

quite different from those in mineral soils. Relative to an agricultural field, the fact that they are potted results in a direct effect of container geometry on the resulting prevailing physical properties.^[1] Growing media have therefore specific norms to guide their manufacturing and for diagnosis of plant growth problems.^[1] Some media are relatively friable, and their properties are affected by their preparation, processing, and handling prior to potting. Moreover, once potted, their properties continue to evolve due to substrate subsidence and decomposition during use. Consequently, their properties must be measured with methods adapted to their specific context of use (see the section “Testing of Growing Media” for testing). The concept of particle size distribution, extensively used in mineral soils to relate texture to physical properties like saturated hydraulic conductivity, available water, and bulk density among others, has limited use as a quality criterion with organic growing media. Its success has been essentially limited to detecting severe aeration problems, but particle size distribution has remained a poor predictor of other properties and growth performances, as the shape of coarse fragments (>10 mm diameter and larger) can result in aeration limitations compared to intermediate-sized fragments and because of the interactive effect of particle shape on mixes. The most commonly used physical properties are related to aeration and available water in growing media, as they are related to plant performances. Specifically, such properties are related to the storage and exchange of air (e.g., air-filled porosity, gas diffusivity), the drainage properties (e.g., hydraulic conductivity), the availability of the water for plant growth (e.g., available water), and the degree of compaction as per its bulk density, among others. Air-filled porosity is the most often referred index of aeration processes, with recommended values being in the range of 0.20–0.30 cm³ cm⁻³ at -1 kPa. Studies on aeration processes confirmed through the clear advantage of measuring gas diffusivity to relate the quality of the substrate to plant growth. Moreover, the very high respiration needs of some organic growing media should also be included, as competition for oxygen may limit crop performance. An excellent substrate should also have an equivalent proportion (0.20–0.30 cm³ cm⁻³) of water available (defined as the proportion of water between container capacity, typically -1 kPa, and the beginning of stress for plant growth set at -10 kPa). The lower limit of water availability is reached at -10 kPa, as typically water in peat and peat-soil mixes becomes less available to plants (first signs of stress) at a higher range of water potentials (-5 to -15 kPa), with permanent wilting in the range of -30 kPa, compared to that in mineral soils (-10 to -60 kPa) for first sign of wilting, and then to -1500 kPa for permanent wilting, respectively. Hence, available water is and should typically be calculated using -10 kPa as the lower limit. When performing

these evaluations, the water desorption curve should be described with the van Genuchten–Durner approach, incorporating wetting angle changes during the desorption and rewetting process and taking into account the hysteresis phenomenon, which being sometimes extraordinarily large in organic media.^[1]

CHEMICAL AND BIOLOGICAL PROPERTIES

For the evaluation of chemical properties of a growing medium, the most important criteria are pH and the nutrient content of macroelements and microelements. Significant variations in pH can occur for some substrates, depending on their provenance. Therefore, corrections are often necessary. The pH plays an important role in plant substrates, determining the availability of various nutrients. Although plant pH requirements differ, for most plants optimal nutrient availability occurs when the pH value of a nutrient solution is between 5.5 and 6.0. Higher values nearly always reduce the solubility of phosphates, iron, and most micronutrients. Moreover, high pH values (>7.5) in the irrigation water are undesirable, given the probable precipitation of calcium and magnesium carbonates, as well as orthophosphates, which can clog the drippers.^[2] It is a standard practice to adjust the pH of an acidic growing medium such as peat moss by the addition of limestone. Since the pH of some materials can change during the storage process, it is recommended to analyze materials shortly before using and to adjust the pH value according to plant requirements. This is valid for nutrient levels as well.

Cation exchange capacity (CEC) gives information about the sorption force and buffering ability of a substrate for nutrients. Substrates with high CEC can store more nutrients, and plants are fertilized more intensively. In addition, such substrates buffer the fertilizer or mineral materials better when hard water is used. From a practical point of view, considering the small volumes of growing media used for plant production, continuous fertigation of substrate-grown crops enables the use of different substrates with different CEC. High CEC growing media may lead to nutrient imbalance if not adequately adjusted; however, frequent fertigation can mitigate the negative effects.^[2]

A good growing media must be free from pests and pathogens, be biologically stable, and not be toxic. The use of forestry products as well as immature compost container substrates can involve problems of phytotoxicity. Some of these materials have a protection function and defend, e.g., bark against insects or infections, and can be toxic to other organisms, such as greenhouse plants cultivated in substrates originating from these materials. Different methods such as composting, aging, leaching, washing, mixing, and fertilization are used to reduce or eliminate phytotoxicity properties of growing

Fig. 1 Some materials used for soilless culture and growing media. From left to right: Rock wool, polyurethane foam, expanded shale, volcanic material, open porous clay granulate, expanded clay, perlite, black peat, coarse wood fiber, fine wood fiber, vermiculite, and light peat.

media materials. Some of these methods are also used to reduce the nitrogen (N) immobilization of wood fiber products.^[2]

MATERIALS USED AND GROWING MEDIA CHOICE

An important difference between soil and substrate culture is the limited volume of substrate that can be used, which means a much reduced volume for the root system. As a

consequence, adaptation in cultivation methods, mainly in irrigation, is required.

Some of the growing media used are illustrated in Fig. 1. Table 1 provides an overview of some characteristics for different substrates. A brief presentation of the most used substrates is shown as follows.

A look at the diversity of the existing growing media teaches us that the success of cultivating seedling and transplants in them could be achieved in different ways, and since technical and financial implications are involved, there is no unequivocal scheme for the choice of growing media. A mixture of growing media constituents and additives is generally used in the horticultural industry. Growing media constituents include combinations of different materials, mainly peat and other organic or inorganic materials. Growing media additives include fertilizers, liming materials, and biocontrol or wetting agents. The choice of which material to be used as a growing medium or a component depends on the type of crop to be grown; for instance, some of the materials with high pH, e.g., composted green waste, would not be suitable for ericaceous crops. In addition, seed germination and growth of some sensitive plants are particularly susceptible to high electrical conductivity (EC), and some of the materials, particularly some composted organic wastes, would not be suitable. Crops grown over a long term need stable growing media, as collapse of the growing medium in the pot could cause aeration problems.

INORGANIC SUBSTRATES

Gravel and sand were used in older installations. They are used as components to improve the aeration and give

Table 1 Advantages and disadvantages of materials used as growing medium or as growing media constituents.

Material	Advantages	Disadvantages
Sand	Relatively inexpensive, good drainage ability	Low nutrient- and water-holding capacity
Rock wool	Lightweight and ease of handling, totally inert, nutrition can be carefully controlled	Disposal problems, energy consumed during manufacture
Vermiculite	Lightweight, high nutrient-holding ability, good water-holding ability, good pH buffering capacity, good aeration	Compacts when too wet, energy-consuming product, expensive
Perlite	Lightweight, sterile, neutral in pH, no decay	Low nutrient capacity, energy-consuming product, expensive
Peat	Physical stability, good air and water-holding capacity, low microbial activity, lightweight, low and easily to adjusted pH, low nutrient content	Finite resource, environmental concerns and contribution to carbon dioxide release, increasing cost due to energy crisis, may be strongly acidic
Coconut coir	Physical stability, good air content- and water-holding capacity, low and easily to adjusted pH, lightweight	May contain high salt levels, energy consumption during transport
Bark (well-aged)	Good air content and water-holding capacity	Increasing cost since used as an alternative to fuel and in landscaping
Green compost	Good source of potassium and micronutrients, suppression of diseases, good moisture-holding capacity	Variable in composition, may contain excess salt, high CEC, becomes easily waterlogged
Biochar and hydrochar	Production is energy neutral, helps with carbon sequestration, biologically very stable; wet material can be used for hydrochar; hydrochar has low EC	High production costs; biochar often has high pH, can be dusty; properties vary dependent on feedstock, particularly for biochar

weight to the container in nursery, avoiding plants' fall during strong wind events. The use of polythene-wrapped rock wool, originally produced as insulation in the construction industry, aided by its lightweight and ease of handling, has become the dominant soilless culture system for greenhouse vegetables and is used throughout the world. A complete nutrient solution is supplied through the irrigation system. Besides rock wool, different inorganic substrates such as perlite, tuff, volcanic porous rock, expanded clay granules, vermiculite, as well as synthetic materials have been used as growing media. In addition, organic substrates can be used.

ORGANIC SUBSTRATES

Peat, formed by partial decomposition of sphagnum, other mosses, and sedges, has long been used as a component of standardized growing media, but work from the 1950s and later showed that it could be used as a growing medium in its own right both for container plants and for vegetable and cut flower production. The main advantage of peat as a growing medium is its relative consistency, low nutrient content, and low pH, so that pH and nutrient levels can easily be adjusted to desirable levels. The other advantages of peat are its lightweight, high water-holding capacity, and high air space.

Wood fiber, wood chips, and sawdust are renewable resources from the woodworking industry. All these products are characterized by low water retention, good air content, and high saturated hydraulic conductivity. Wood chips and sawdust are usually used in the proportion of 20–30% (volume basis) in mixtures with other substrate components. However, with an adequate supply of complete nutrient solution, it is possible to use wood fiber alone as a growing medium. A reduction in particle size, an increase in volume weight, and an increase in irrigation frequency are recommended.^[3] Furthermore, a compression of wood fiber substrates in pots is recommended to minimize substrate loss. Additional N fertilization from the beginning of plant cultivation is recommended to overcome N immobilization.^[4]

Composted materials such as green waste and biowaste can be used as a component of a growing medium up to 50%, but not on its own.^[5] The limiting factor regarding the use of composted green waste is its high EC and potassium (K) concentration. There can also be a problem of plant pathogens, human pathogens, and weed contamination if the composting process is not properly conducted, i.e., if the temperature time exposure is not sufficient.

Bark from conifers (soft wood) and deciduous trees (hardwood) can be used as a component of growing medium. Bark has to be composted to eliminate phytotoxins, and N must be added during composting to overcome N immobilization.^[6] The air and water-holding capacity of

the bark can be adjusted by varying the percentage of fine materials (less than 1–2 mm).

Coir is a by-product of the coconut industry and comes from the fibrous husk of coconuts. The powdery material can be used as a growing medium. Most of the coir dust comes from Sri Lanka, India, and Southeast Asia. It can contain high levels of sodium, K, and chlorine, which may need to be leached. Due to its high water-holding capacity and concomitant high levels of aeration due to the cellular nature of coir, rooting of plants is very good.^[7]

Due to environmental concerns and thus pressure on reduced peat usage, there is a strong sentiment on total peat replacement or dilution. Materials that are being used for this are mainly coir, wood fiber, bark, and composted green waste. The addition of these materials to peat can lead to increase in certain nutrient levels, e.g., K in case of composted green waste. The addition of composted green waste can also lead to increase in pH and exchangeable calcium and micronutrients.^[8] In these cases, there can be savings on the nutrients and limestone to be added. However, the addition of some of these materials, e.g., wood fiber, sawdust, and bark can lead to N immobilization.^[4] These materials are generally not as stable as peat. Therefore, stability^[9] and N immobilization measurements should be made before they are added to peats for use as growing media.

NEW DEVELOPMENTS

Despite the high value of peat as a growing substrate, there is a concern with the fact that peat comes from peatland ecosystems, which are important ecosystems for a wide range of wildlife habitats, for water quality and cycle and carbon sequestration. Consequently, a “wise use” approach of peat usage has been adopted, and extensive research is carried out on sphagnum farming and peat bog rehabilitation to balance conflicting demands on peat land use. As a partial or complete replacement for peat, composted materials such as biowaste and bark, coir, and wood fibers will be increasingly used.^[10] The overall increasing use of growing media has resulted in the world demand for peat continuing to grow, despite substantial efforts to find alternatives, and hence, this “wise use” approach is appropriate and much needed. There has been an increasing interest in biochar and hydrochar. Both are lightweight materials and can be produced from many organic feedstocks. Biochar is a form of charcoal, which is manufactured by pyrolysis and can be used as a growing medium or a growing media component. It has a high stability and can have low EC, which is essential for its use as a growing medium. One potential innovative technology is hydrothermal carbonization (HTC). The final product is similar in structure to biochar produced by pyrolysis, however, in contrast to biochar production; the HTC process requires just moderate

temperatures and pressures and is usually used for materials with high water content, e.g., plant materials and waste.^[10] With HTC, heavy metals and EC in the waste and the solid fraction are reduced during processing,^[11] but the presence of volatile fatty acids can render them toxic to seedlings and young plants, which be overcome by simple pretreatment.

TESTING OF GROWING MEDIA

As seen in the previous section, numerous raw or processed products have been offered as a growing medium or as a component of growing media. Often they are waste products from the agricultural and forestry industry, e.g., coir, green waste, wood fiber, and sawdust. Some of these materials have to be processed further by composting (green waste) or leaching (coir). Laboratory tests are necessary to check the suitability of materials for quality control and for fertilization advice. The tests used are chemical, physical, and biological. There has been much advancement in the testing of growing media, and new methods have been developed, e.g., pH, EC, available nutrients, stability, and phytotoxicity, some of which differ from those used in conventional soil analysis. Many of these have been developed under the auspices of the European Committee for Standardization involving cooperative testing among a number of European laboratories. A good example is the development of stability and phytotoxicity tests for growing media and soil improvers.^[9] For physical characteristics, methods limiting disturbance are also prescribed to limit any effect on the properties.^[1] Methods that compact samples prior to analysis by the use of a standard weight for compaction or that apply a suction prior to measuring the characteristics of potted substrates are in use. The many steps following the processing and mixing of the substrate, which involves loosening, filling, and planting in various containers, may affect the resulting physical properties, and even if methods exist that compact samples to a bulk density similar to that found in the container, preferable approaches include putting instrumentation such as tensiometers, and water content probes directly into the container or weighing of potted substrates should be preferred. Permeameters should also be used on potted substrates. Driving cores into the substrates is problematic and extracting material from a container and trying to repack cores is unlikely to achieve a representative sample. Hydraulic processes linked to water storage and exchange are partly a function of container capacity (the equivalent “field capacity” for substrate in container), itself related to container geometry as described elsewhere.^[1] Hence, drainage will depend very much on container configuration and in practice, substrate water pressure will typically be in the range of -0.5 to -1.5 kPa after saturation and drainage,

clearly different from matric potential values encountered in agricultural fields (-10 to -33 kPa). As a result, characterization of volumetric water content at container capacity, and of air-filled porosity, should be performed directly on the pot equilibrated at container capacity. This also applies for unsaturated hydraulic conductivity and gas diffusivity determination. Such measurements must be repeated at specific intervals in the container itself inasmuch as possible to take into account the dynamic changes of physical properties that are occurring in growing media, the rooting effect and the effect of container configuration.^[1]

CONCLUSION

A major advantage of growing media is that it provides a root environment relatively free of pathogens at the start of the crop cycle or which can contain beneficial micro-organism. They are made of organic or inorganic components, of variable price, quality, and availability. A high proportion of them are made of peat or coir but important successful progress have been made to increase the proportion of compost in them. When the growing medium has the correct physical properties and nutrient supply is close to optimum, the net results are large increases in yield and improved product quality. This has especially been the case when combined with improved growing methods, carbon dioxide supplementation, and computer environment control. However, cultivation systems are expensive to install and need a high degree of technical expertise on the grower side. Therefore, they have mainly found applications in the production of high-value crops of fresh vegetables or ornamentals under protection, and also in outdoor containerized nursery stock production. They expand to new fields of application like strawberry and raspberry production.

Abstract

Gully erosion is prevalent throughout the world and is defined as erosion in channels where runoff accumulates and removes soil from this channel area. Gullies can be divided into ephemeral gully and classical gully depending on the obvious differences in scale. New kinds of techniques have been developed for the dynamic gully erosion process research for generating high resolution topography. There is still a long way to go to predict gully erosion before successfully quantifying the gully dynamic evolution process and validating and calibrating suitable parameters for calculating gully erosion rate. Reasonable gully control practices can well prevent gully erosion in various environments.

INTRODUCTION

Gully erosion is defined as erosion in channels where runoff water accumulated and removes soil from this channel area.^[1] Gully erosion is prevalent throughout the world. In 1939, Bennett^[2] estimated that 200 million active gullies were in existence in the United States. These gullies range in depths from 0.3 to 0.6 m to as much as 50 to 100 m. The severe erosion in 1930s prompted the U.S. government to take actions to control erosion, and successful results are well known all over the world. Gullies remove portions of land from production completely and fragmentize the landscape making it difficult for vehicles or farm machinery to move across. Gully erosion significantly reduces land quality and value and also contributes to downstream sedimentation problems.^[3] Despite the fact that a gully can be viewed as a part of the natural drainage system, it is different from a stream channel due to its intermittent flow triggered only by rainfall events.

Gullies often develop from intense erosion caused by flow over a steep overfall at the top of the gully. This overfall, called a headcut, moves upstream in a natural drainage way, and it can be initiated off-site and move into a field. Gullies can also be enlarged by lateral erosion, sloughing of their sidewalls, and cleaning out of debris by flow in the gullies. Subsurface flow through the gully walls can significantly reduce soil strength and accelerate gully erosion.^[3]

Depending on the scale, gullies are divided into two types—ephemeral gully (Figs. 1 and 2) and classical gully (Figs. 3 and 4). Ephemeral gullies are wider and deeper than rills, but they can be tilled across and filled in partially or completely. Although the ephemeral gully can be filled in or obliterated by tillage operations, it tends to reappear later at the same location because the depression it has formed on the landscape will concentrate the runoff. Classical gullies are eroded channels too large to cross and obliterate with tillage equipment. Table 1 shows the comparative characteristics of rill erosion, ephemeral gully erosion, and classical gully erosion.^[4]

EPHEMERAL GULLY EROSION

Ephemeral gully erosion is referred to as concentrated-flow erosion, mega-rill erosion^[4] or shallow gully erosion.^[5] The ephemeral gully erosion is the process of overland flow converging into a few major natural waterways, detaching soil particles from the waterway boundary, and transporting sediments downstream. Ephemeral gullies are the main drainage systems for a field, and most runoff and sediment are discharged from fields through these channels. The contribution of ephemeral gully erosion varies geographically. The U.S. Department of Agriculture–Natural Resources Conservation Service (USDA-NRCS) estimates from 19 U.S. states (Table 2) showed that ephemeral gully

Fig. 1 Ephemeral gully in the United States.

erosion contributed to 17% of total soil loss in New York state and to 73% in Washington state.^[6,7] Ephemeral gully erosion also affects the loess belt and Mediterranean region of Western Europe and the Loess Plateau of China. Ephemeral gully erosion contributes to at least 10% of the total soil loss in loess area in Europe^[8] and 35% of the total soil loss in the Loess Plateau of China. Most erosion in ephemeral gully channels is from rainstorms soon after seedbed preparation. As time progresses through the growing season, soil consolidates and these channels become less erodible. Many ephemeral gullies begin at a third to halfway down the slope, and then extend and grow in both the directions.

The following factors have been identified for the development of ephemeral gullies: 1) critical slope length and slope gradient that are dependent on slope characteristic and crop row direction and vegetation cover; 2) occurrence and depth of a fragipan; 3) agricultural practices, principal row direction, and timing of cultivation; and 4) timing and total amount of precipitation.^[7,9]

CLASSICAL GULLY EROSION

Classical gullies are those that are too large to be filled in or obliterated through tillage operations. The qualities of sediment moved from gully system in loessial regions are highly variable. Gully erosion contributed 10–30% of

Fig. 2 Ephemeral gully in China.

Fig. 3 Classical gully in China.

annual sediment yield in the deep loess of western Nebraska from 1937 to 1952.^[10] At the Loess Plateau of China, gully erosion contributes about 60% of total sediment yield in the hilly gully region and 90% of total sediment yield in the high plateau with deep cutting and large gully region (Fig. 3). The contribution of gully erosion to total sediment yield also changes with year, dependent upon annual precipitation and the timing of storms. Gully channel formation is very rapid during the period of gully initiation, when morphological characteristics of a gully (such as length, width, area, and volume) are far from stable. This period is relatively short, about 5% of a gully's lifetime. For the most part of a gully's lifetime, its size is nearly stable, except near the headcut area.

Main factors affecting gully development in loessial regions are watershed size, runoff, the distance from the top of the gully to the watershed boundary, gully channel gradient, surface material, substratum moisture, and vegetation cover.

TECHNIQUES OF MEASUREMENT

Aerial photography is widely used for making accurate and repetitive measurements of gully development.^[11] Sequential stereo photographs taken at critical intervals provide excellent information for assessing gully development. Field survey is also used to quantify gully geometry. Nevertheless, measuring gully geometry, especially at different

Fig. 4 Classical gully in the United States.

Table 1 Comparative characteristic of rill erosion, ephemeral gully erosion, and classical gully erosion.^[4]

Rill erosion	Ephemeral gully erosion	Classical gully erosion
Rills are normally erased by tillage, do not usually reoccur in the same place.	Ephemeral gully are temporary features, usually obscured by tillage; recur in the same location.	Gullies are not obscured by normal tillage operations.
May be of any size but are usually smaller than ephemeral gullies.	May be of any size but are larger than rills and smaller than the permanent gullies.	Usually larger than ephemeral gullies.
Cross-section tends to be narrow relative to depth.	Cross-section tends to be wide relative to depth. Sidewalls are frequently not well defined. Headcuts are usually not readily visible and are not prominent because of tillage.	Cross section of many gullies tends to be narrow relative to depth. Sidewalls are steep. Headcuts are usually prominent.
Flow pattern develops as many small disconnected parallel channels ending at ephemeral gullies, terrace channels, or where deposition occurs. They are generally spaced and sized.	Usually forms a dendritical pattern along depression watercourses, beginning where overland flow including rills converge. Flow patterns may be influenced by tillage, crop rows, terraces, or other man-related features.	Tend to form a dendritical pattern along natural watercourses. Non-dendritical patterns may occur in road ditches, terrace, or diversion channels.
Occurs on smooth side slopes above drainage ways.	Occurs along shallow drainage ways upstream from incised channels or gullies.	Generally occurs in well-defined drainage ways.
Soils is removed in shallow channels, but annual tillage causes the soil profile to become thinner over the entire slope.	Soil is removed along a narrow flow path, typically to the depth of tillage layer where the untilled layer is resistant. Soil is moved into the voided area from adjacent land by mechanical action (tillage) and sheet and rill erosion, damaging area wider than the eroded channels.	Soils may be eroded to depth of the profile and can erode into soft bedrock.

times to monitor the gully development, is laborious. From 2005, new remote-sensing techniques have been developed for gully erosion research for generating high-resolution topography. They are the unmanned aerial vehicle (UAV),^[12] the time-of-flight (ToF) cameras (or range cameras),^[13] total station and Real Time Kinematic (RTK) survey, overlapping photographs (stereo pair),^[14] airborne and terrestrial light detection and ranging (LiDAR).^[15]

The UAV, commonly known as a drone, is an aircraft without a human pilot on board. It has integrated autopilot technology, which gives it semi or fully autonomous navigation, flight control, and image acquisition capabilities.^[12] The ToF cameras are a new generation of active sensors, which allow the acquisition of three-dimensional (3D) point clouds without any scanning mechanism and from just one point of view at video frame rates. The working principle is the measurement of the ToF of a signal emitted by the device toward the object to be observed, with the advantage of simultaneously measuring the distance for each pixel of the camera sensor.^[13] A total station is an electronic/optical theodolite integrated with a distance meter whereby coordinates of an unknown point relative to a known coordinate can be determined as long as a direct line of sight can be established between the two points. The basic concept of RTK is to have a base station receiver set on a point with known coordinates in the project site. Overlapping photographs (stereo pair) of a certain area of interest are acquired. Control targets within the stereo pair are surveyed with an electronic total station. Bearings (horizontal and vertical angles) to the targets from multiple stations are converted to 3D coordinates using intersection and

triangulation methods.^[14] Ground-based LiDAR systems provide detailed multitemporal analysis of microtopography. With LiDAR, it is possible to obtain digital terrain models, estimate soil roughness, perform volume calculations, and terrain topography changes.^[15]

PREDICTION OF GULLY EROSION

To separately predict ephemeral gully erosion and gully erosion, topographic threshold models were first given all around the world. Critical topographic conditions, expressed by local slope gradient and drainage area, can well describe the difference between ephemeral gully erosion and gully erosion.^[16]

The ephemeral gully erosion model, a computer program to provide estimates of the average annual soil loss removed from a single ephemeral gully, was developed by the USDA-ARS and USDA Soil Conservation Service.^[17] However, it showed poor adaptability around the world,^[18–20] and seeking and developing suitable physical process-based model and topographical index-based model in various environment needs more research.^[21]

Two types of models have been developed to predict gully development: 1) Dynamic models to predict rapid changes of gully morphology at the initial period of gully development with active headcut and channel expansion, which are based on the solution of the equations of mass

conservation and gully bed deformation; and 2) Static models to estimate final geometric parameters of stable gullies, which are based on the assumption of final morphological equilibrium of a gully.^[22]

The dynamic and static models were verified on the data of gully morphology and dynamics from Yamal Peninsula, Russia, and New South Wales, Australia. However, shortcomings like several parameters of gully morphology needed to be input before running the model, makes it hard to be widely used in different erosion environments. There is still a long way to go to predict gully erosion before successfully quantifying the gully dynamic evolution process and validating and calibrating suitable parameters for calculating gully erosion rate.

CONTROL OF GULLY EROSION

There are different practices to prevent or mitigate ephemeral gully formation and erosion. Conservation tillage is an excellent soil conservation practice for preventing ephemeral gully formation in agricultural fields. In areas where ephemeral gullies have formed, vegetation control, such as grassed waterways and vegetation barriers are often used to reduce their further development. Sometimes, a retention structure is built within gully channels to trap sediment.^[7]

Because many classical gullies have become a permanent landscape feature, stabilizing the channel banks and

Fig. 5 Classical gully control.

headcut area is the primary goal. Establishment of vegetation along the channel banks and headcut area is most effective in preventing classical gully growth. For large gullies such as those at the Loess Plateau of China, terracing on the gully slope and building retention structures (like check dam) in the gully channels are widely used for controlling classical gully erosion (Fig. 5).

Gypsic Soils

Juan Herrero

Department of Soils and Irrigation, Laboratory for Agronomy and the Environment (DGA-CSIC), Zaragoza, Spain

Jaime Boixadera

Department of Agriculture, Livestock, and Fisheries, Government of Catalunya, Lleida, Spain

Abstract

Gypsic is applied in a broad sense to those soils whose behavior and appearance are dependent on their gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) content either in the entire profile or in a particular horizon. High amounts of gypsum in soils are more likely to occur in dry climates.

GYPsic SOILS IN THE WORLD

The world distribution of gyprock outcrops and the solubility of gypsum restrict the extensive occurrence of gypsic soils to the dry regions (Figs. 1 and 2). These soils are distinct and recognized by local populations, as well as by early pedologists, in areas such as Northern Africa, the Middle East, and Spain. Most soil classification systems have the formative element *Gyps*. The extent of soils with gypsic or petrogypsic diagnostic horizons^[1] in Africa, Asia, the Near East, Europe, and the United States has been estimated at 207 million ha,^[2] and broad gypseous areas also occur in Australia, Mexico, and South America. These soils and other gypsiferous surface formations interact in global cycles through calcium and the bicarbonate equilibria with the atmosphere and water,^[3,4] processes also involving respiration. Gypsic soils deserve an environmental valuation due to the pedodiversity protection and plant endemisms produced by selective forces not yet established.^[5]

OCCURRENCE OF GYPSUM IN SOILS AND THEIR RELATED PROPERTIES

The semisolubility of gypsum in water (~2.6 g/L) controls the occurrence of gypsum in soils. The soil solution or the water extracts of gypsic soils have an electrical conductivity of 2.2 dS/m or more if soluble salts with no common ions are present. The leaching of gypsum out of the profile is common in wet climates. The low solubility of gypsum enables its transport from gyprock or other primary sources, its redistribution in the soil by dissolution/precipitation, and its permanent presence as a significant soil component in dry environments or in specific geomorphic positions. Moreover, the size of some pedogenic or sedimentary

gypsum crystals allows their transport by wind from bare ground surfaces. Gypsum in soils can also result from other natural or artificial materials containing sulfur, e.g., rain, industrial products, or mine spoils, but in these cases gypsum is a minor soil component.

Gypsum, even in small quantities, can prevent clay dispersion and soil degradation. The effect is due to the displacement of sodium ion from the cation exchange complex of the soil by the calcium ions (Ca^{2+}) released by the gypsum. This is one of the reasons for the use of gypsum as a soil amendment not only for sodic soils but also to avoid soil sealing and crusting under irrigation with sodic or with low electrical conductivity waters.^[6] Gypsum is also a soil acidity ameliorant.^[7,8] Plants are not stressed by the osmotic potential generated by gypsum, and this fact together with the beneficial effect on crops with high calcium or sulfate requirements must be taken into account when land evaluation deals with gypsiferous soils.^[9] In gypsic soils, a constant osmotic potential generated by the gypsum exists over all the range of soil moisture contents; it may reach up to -80 kPa and it has a mild effect on plants quite different from the osmotic effect in saline soils because the last one is several times higher even for the very slightly saline soils (electrical conductivity in the saturation extract = 2–4 dS/m at 25°C).

HYPERGYPSIC SOILS

The name of hypergypsic was coined for a subsurface diagnostic soil horizon with 60% or more gypsum,^[2] and later reused with genetic meaning.^[10] Those soils having gypsum as a major component can also be named hypergypsic.^[11] These types of soils appear on gyprock outcrops or close to some other gypsum source, commonly in arid climates.^[3] In these conditions, gypsum is not transitory and

Fig. 1 World distribution of gypsic soils.

Source: Prepared from data contained by Eswaran & Zi-Tong,^[2] Alphen & Ríos,^[12] Boyadgiev & Verheye,^[13] Bridges & Batjes,^[14] FAO,^[15] Fierotti, Dazzi, et al.,^[16] Heinze & Fiedler,^[17] Jacob,^[18] Laya,^[19] Macau & Riba,^[20] Mashali,^[21] Mees,^[22] Nettleton et al.,^[23] Watson,^[24] many of the documents quoted by Herrero & Porta,^[3] and from authors' studies.

can constitute the soil groundmass, supporting pedological processes such as the redistribution of silty or clay-size carbonatic materials in the profile.^[25] The growth of gypsum crystals is displacive, resulting in a mixing of the soil

components: This can be illustrated by the disturbance and comminution of lutitic geological materials leading to C horizons^[26] or by the mechanical weathering of the parent gyprock.^[27] Many hypergypsic horizons show an isles

Fig. 2 Aerial view of the valleys carved with a fingered pattern in the gyprock surrounding Zaragoza (Spain). These valleys are flat-bottomed because of their filling during the Quaternary with materials from the soils on the slopes. Transversal dry-stone walls were built to control the erosion and to capture water in the bottoms. Deep gypsic soils there only permit poor barley yields even in the favorable years, because of the aridic soil moisture regime. The hills have shallow discontinuous gypsic soils, with shrub cover in the shaded slopes.

Source: Photo by O. Artieda, 1997.

fabric under the microscope, i.e., masses of non-gypsic fine material embedded in a gypsic pedofeature or the gypsic pedofeature can even be continuous producing a horizon with gypsic groundmass.^[11] In the field, these horizons feel either “gritty,” “flour-like,” or like “hard-bread crumbs” composed of sandy or coarser gypsum lentils, microcrystalline gypsum, or travertine gypsum, respectively.^[28,29] Some of these horizons can qualify for petrogypsic^[1,10] if a certain degree of cementation is attained. Commonly gypsic soils occur in Holocene surfaces, but the ones with cemented horizons have been found in Pleistocene surfaces.

For sand-sized or smaller grains, the distinction between pedogenic or geologic gypsum is often unfeasible even under the microscope.^[30] Moreover, this distinction lacks agricultural or environmental interest, at least in the gypsic soils in areas with ubiquitous gypsum. This makes it possible to argue against the incorporation of the distinction between primary and secondary gypsum into the concept of hypergypsic^[10] and even in the definitions of the gypsic and petrogypsic diagnostic horizons.^[1,10]

CONSTRAINTS TO THE USE OF GYPSIC SOILS

The presence of gypsum must not be confused with the osmotic effect of soil salinity, even though gypsic soils can also be saline, as is the case in playa- or sabkha-like^[31] environments or in some alluvial plains with incomplete drainage. In fact, gypsum is often used as an amendment in sodic soils to allow salt leaching.

Physical and Engineering Constraints

A large amount of gypsum in soils implies minor contents of clay minerals and other components having high water and nutrient retention capacity. Water is the main limitant to plants' life, thus in arid climates the soil water-holding capacity is decisive for life. In gypsic soils, this capacity is controlled by the gypsum grain size. Moreover, the soil exploration by roots can be hampered by massive gypsic layers.^[2] Drought is severe for plants in gypsic soils grazed or sown with barley or other annuals, except where irrigation or rain is frequent during the growing season.

Sparse shrubs or trees, also ants or other animals, often take advantage of cracks, or shallow karstic cavities in gyprock where lower temperatures and some moisture are available in arid environments.

Dissolved gypsum attacks concrete and iron, hindering, together with karstic phenomena, the construction of irrigation canals and tunnels. These problems plus the sinkholes by dissolution make flood irrigation of gypsic soils difficult or impossible;^[12] although sprinkler or drip irrigation techniques and the use of plastics in agriculture have overcome some of the obstacles to the irrigation of these soils. The water return flows from irrigated gypsic soils

are saturated with calcium and sulfate, limiting the urban or industrial reusability of these waters.

Fertility Constraints

Gypsic soils support forests or shrubs under appropriate climatic and management conditions and have been grazed and cultivated from times immemorial in a sustainable manner, but fertility is a matter of concern for intensive agriculture in gypsic soils. One favorable point is that, in contrast with other anions, no luxury consumption of sulfate by plants occurs, as was earlier reported^[32] from pot experiments. Sulfur is an essential element, and sulfate its main source for plants, but many different sulfur-based anions can occur in the soil depending on local or temporal conditions of pH, redox, microbial action, etc.^[33] making the assessment of the role of gypsum in soil fertility difficult. The relationship between sulfate and phosphate adsorption^[34] must be remembered, but probably the main fertility problems in gypsic soils are related to their low nutrient retention capacity and to the high amounts of Ca^{2+} in the soil solution (gypsum is over 100 times more soluble than calcite), reducing the availability of P for plants or inducing chlorosis in sensitive fruit trees. These and other constraints related to nitrogen and other nutrients in gypsiferous soils have been reviewed by FAO;^[2] this work also gives an overview on the effects of gypsum on several crops. Many knowledge gaps in this subject are due to the limited research conducted about fertility in gypsic soils and to the failure of some experiments to meet the analytical procedures^[35] required for gypsiferous soils.

Gypsic Soils: Gypsum Formation

Ahmet R. Mermut

Department of Soil Science, University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Hossein Khademi

Isfahan University of Technology, Isfahan, Iran

Abstract

Gypsiferous soils occur commonly in arid and semiarid regions with less than 400-mm annual precipitation. Over 200 million hectares of gypsiferous soils occur in the world. Gypsum and calcite often occur together in soil. They have a common ion (calcium), and the solubility of each of calcite and gypsum is determined by the presence of either mineral. The origin of sulfate ions in the soil solution can be different, in some circumstances, because of the presence of S-rich minerals such as sulfides in the parent materials. Gypsiferous soils are severely prone to soil erosion and the hydraulic conductivity of the soil is generally low, and gypsic horizon can also act as a barrier for root penetration. High amounts of gypsum also affects its soil fertility.

INTRODUCTION

Soils containing sufficient amount of gypsum to interfere with plant growth are generally defined as gypsiferous soils.^[1] These soils occur commonly in arid and semiarid regions with less than 400-mm annual precipitation.^[2] Many gypsiferous soils are found in densely populated areas, where irrigated agriculture is necessary for food production (Table 1).

GENESIS AND ORIGIN OF SULFATE

Gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) is the dominant mineral in gypsiferous soils. Anhydrite (CaSO_4) is mainly associated with marine evaporites and is rapidly converted to gypsum when it is exposed to normal soil environment. Bassanite or hemihydrate ($\text{CaSO}_4 \cdot 0.5\text{H}_2\text{O}$) is an intermediate form between gypsum and anhydrite. These two mineral phases have been identified at soil surfaces as dehydration products of gypsum under highly dry conditions.^[3] Both pedogenic and inherited gypsum may be found in the soil.

Carter and Inskeep^[4] reported that pedogenic gypsum accumulation is high in soils with high content of total gypsum and relatively long period of soil formation. Gypsum is more soluble than calcite and normally occurs in: 1) a dry moisture regime; 2) regions with marked seasonal moisture fluctuations; and 3) a relatively short timescale, compared with that of calcite. Upward movement of water by capillary rise and subsequent evaporation are important factors responsible for the generation and accumulation of gypsum near the soil surface.^[5] Downward movement of

gypsum may occur following the incomplete wetting of the soil.^[6]

The origin of sulfate ions in the soil solution is, in some circumstances, a result of the presence of S-rich minerals such as sulfides in the parent materials. By weathering and oxidation, the sulfur in these minerals is transformed into sulfuric acid, which, in calcareous soils, reacts with calcite or dolomite to form gypsum.^[7] As shown in Eqs. 1 and 2:

The pedogenic gypsum of gravely gypsic horizons mostly occurs as pendants below pebbles (Fig. 1). In nongravely materials, it occurs as whitish, powdery or crystalline, soft masses, or diffused in the soil matrix at a certain depth (Fig. 2). The topographic setting strongly influences the quantity and the location of gypsum in the soil.^[8]

Geological formation is the origin of most gypsiferous soils particularly in Central Asia, Middle East, North Africa, the Southwestern United States, southern Spain, Northern Mexico, and Australia.^[9] Inherited gypsum can be redeposited by wind or water in new locations.^[3,5] Eolian deposits of gypsum are well known in the Southwestern United States, North Africa, and southeast Australia.^[5]

Watson^[8,10] uses the term *gypsum crust* to describe gypsum accumulation at or within about 10 m of the land

Table 1 Global distribution of gypsiferous soils.

Region	Gypsiferous soils (area × 1000 ha)
Africa	50,248
Asia	67,538
Australia	23
Europe	3,896
Middle East	76,721
North America	2,500
Total	200,926

surface from 0.1 to 5.0 m thick containing more than 15 wt. % gypsum and at least 5 wt.% more gypsum than the underlying bedrock. He also states that desert gypsum crusts are of three main types: 1) shallow-water evaporites; 2) subsurface crusts; and 3) surface crusts.

Gypsum and calcite often occur together in soil. They have a common ion (calcium), and the solubility of each of calcite and gypsum is determined by the presence of either mineral. As the partial pressure of carbon dioxide ($p\text{CO}_2$) affects directly the solubility of calcite, this can also indirectly affect the solubility of gypsum. Decreased acidity and SO_4^{2-} activity favor the formation of calcite at the expense of gypsum. An increased CO_2 partial pressure results in a shift of the calcite stability field into the gypsum field. Gypsum is too soluble to persist in soils, unless the SO_4^{2-} concentration is more than 10^{-2} M.^[12]

During evaporation of a solution containing Ca^{2+} , CO_3^{2-} , and SO_4^{2-} , calcium carbonate precipitates until saturation with respect to gypsum is reached. After that, both calcium carbonate and gypsum precipitate simultaneously and the composition of the solution remains unchanged. Coprecipitation of gypsum and calcite is unavoidable if a solution is evaporated to dryness, although the initial precipitate is a single mineral.^[13,14] As a result of saline groundwater migrating upward, less-soluble mineral (calcite) precipitates first and then coprecipitation of both

Fig. 2 Gypsum occurring as whitish, powdery or crystalline, soft masses in a calcic argigypsic soil from Central Iran.

minerals occurs. Because gypsum is more soluble, it can move a longer distance in soil solution and precipitates near the soil surface or inside the profile. The reverse sequence (descending mode) may also occur^[4] and is attributed to leaching. However, it seems that under arid conditions, leaching may not occur, except in some closed depressions.

GLOBAL DISTRIBUTION OF GYPSIFEROUS SOILS

Gypsiferous soils are found in arid and semiarid areas of the world. [Table 1](#) shows the worldwide distribution of gypsiferous soils in the world. The total amount in this table is more than double that was estimated in several previous publications. Over 100–150 million hectares areas of gypsiferous soils occur only in the Middle East and Central Asia. Iran alone has more than over 25 million hectares of gypsiferous soils; therefore the estimates in [Table 1](#) may still be an underestimate.

PROPERTIES OF GYPSIFEROUS SOILS

Where gypsum particles are present in the surface layer, their types, amount, and the degree of crystallization, the depth of gypsum layer, and its degree of induration have a profound impact on the physical and physicochemical properties of the soil. Gypsiferous soils are weakly aggregated because the cohesive forces attracting single soil

Fig. 3 Severely eroded gypsiferous soils from Central Iran.

particles are very weak.^[4] Consequently, gypsiferous soils are severely prone to erosion (Fig. 3).

In the presence of petrogypsic horizon, the hydraulic conductivity of the soil is generally low and this horizon can also act as a barrier for root penetration. Keren et al.^[15] reported that the reduction in hydraulic conductivity of the soils that contain gypsum is mainly because of mechanical plugging of soil pores by the small gypsum particles. When pedogenic gypsum accumulates in the subsurface horizons to the extent that the soil matrix becomes plugged, the growing gypsum crystals tend to interlock and indurate the horizon, causing a serious impediment to root growth. Abrukova and Isayev^[16] attribute the difficult workability in the soil, i.e., digging trenches, to the hardness of the gypsic horizon when it is dry. Gypsum reduces the total water reserve of the soil because gypsum itself has low water holding capacity.^[17]

High amount of gypsum in soils also affects its fertility. In addition, the availability of some of macronutrients such as Phosphorous (P), potassium (K), and magnesium (Mg) and also micronutrients such as molybdenum (Mo) is affected by the presence of gypsum. Gypsiferous soils require large quantities of nitrogen (N), P, and K for crop production.^[18] P is one of the micronutrients that is immobilized by gypsum in soil through the formation of different calcium phosphate compounds such as octacalcium phosphate and hydroxy apatite.^[9] The increase in Ca concentration in solution usually leads to a decline in K and Mg uptake by plants.^[5] Different plants have different ability to tolerate high levels of gypsum in the soil. Alfalfa (*Medicago sativa*), e.g., usually maintains an optimal ionic composition regardless of the gypsum content. In contrast, plants such as corn (*Zea mays*) are highly sensitive to gypsum.

Olsen and Watanabe^[19] reported that the added gypsum to sodic soils decreases Mo concentration and increases that of iron, manganese, and zinc in sorghum (*Sorghum bicola*). Singh and Taneja^[20] reported that

addition of gypsum to reclaim the salt-affected soils in India released $\text{NH}_4\text{-N}$ and $\text{NO}_3\text{-N}$ than control. Beneficial effects of gypsum on N mineralization in the soil may be a result of stimulation of microorganisms and/or neutralization of toxic salts.

CONCLUSION

Gypsiferous soils occur commonly in arid and semiarid regions with less than 400-mm annual precipitation. Over 200 million hectares of gypsiferous soils occur in the world. Gypsum and calcite often occur together in soil. They have a common ion (calcium), and the solubility of each of calcite and gypsum is determined by the presence of either mineral. The origin of sulfate ions in the soil solution can be different, in some circumstances, because of the presence of S-rich minerals such as sulfides in the parent materials. Gypsum is too soluble to persist in soils, unless the SO_4^{2-} concentration is more than 10^{-2} M.^[12] Gypsiferous soils are severely prone to soil erosion and the hydraulic conductivity of the soil is generally low, and gypsic horizon can also act as a barrier for root penetration. High amount of gypsum also affects its soil fertility. These soils require large quantities of N, P, and K. Under irrigation, variety of crops can be grown in gypsiferous soils.

Hard-Setting Soils

Richard S.B. Greene

*Fenner School of Environment and Society, Australian National University,
Canberra, Australian Capital Territory, Australia*

Abstract

The problem of hard-setting soils is increasingly being recognized as a widespread form of land degradation in Australia and overseas. Hard setting is a characteristic of soil horizons, usually cultivated seedbeds, which contain unstable soil aggregates. The instability of surface horizons in Australia is usually related to low levels of soil organic matter and/or high levels of exchangeable sodium (often remaining from when the profile was affected by salinity). Under rapid wetting by either rainfall or irrigation, the aggregates collapse, the seedbed slumps, and upon drying, a hard, structureless mass of soil results. In surface horizons, it causes problems with infiltration, aeration, and seedling emergence. Lower in the profile, cohesive horizons, which are a form of hard setting, can also occur and cause problems of root elongation and water uptake. This entry discusses the occurrence of hard-setting soils, and the soil properties and processes that lead to the phenomena of hard setting. Methods for the assessment and management of hard-setting soils are also presented.

INTRODUCTION

Hard setting is a characteristic of soil horizons, usually cultivated seedbeds, which contain unstable soil aggregates. Under rapid wetting by either rainfall or irrigation, the aggregates collapse, the seedbed slumps, and upon drying, a hard, structureless mass of soil results. The change of structure is because of the breakdown of the soil aggregates under rapid wetting into microaggregates <250 μm diameter by a process called slaking.^[1] Hard-setting soils may also have poor physical properties because of the breakdown of their soil aggregates by the process of clay dispersion.^[2] Hard setting is a widely occurring problem, as most soils (apart from well-structured clays, organic soils, and sands) can undergo hard setting. Even though it is usually associated with the A horizon, it can occur in any horizon, thus causing a range of management problems. Mullins et al.^[3] and Blackwell^[4] have reviewed the topic of hard setting. This entry discusses the occurrence, formation, assessment, and management of hard-setting soils.

OCCURRENCE AND PROCESSES OF FORMATION

Generally, the term hard setting has been used only in Australia and was first used by Northcote^[5] in his soil-classification system. It is a widespread phenomena in Australian soils—e.g., in the new Australian classification developed by Isbell,^[6] of the 14 orders recognized, only the Organosols (soils with organic horizons), Podisols (deep

sands), and probably the Calcarosols (calcareous soils) can be generally assumed to be non-hard-setting soils. Internationally, the conditions also exist for hard-setting soils, but due to the lack of a common definition, they are harder to recognize. In Brazil, dense cohesive subsoil horizons occur at a range of depths from 0.2 to 1.42 m and may be considered to be similar to the hard-setting surface horizons described in Australia.^[7]

Even though the soil properties that predispose a soil to surface crusting and hard setting may be similar and involve the same processes (such as slaking and dispersion), the phenomena apply to different thicknesses of the seedbed. Crusting occurs when surface aggregates breakdown on wetting (usually under droplet impact) to form a hard, dense, structureless mass at the soil surface, often only a few millimeters thick. Hard setting, however, involves a much greater thickness of material, which commonly includes not only the A1 or Ap horizon but also the A2 (E) horizons, which may be bleached. Therefore, in some soils, the depth affected by hard setting may be up to 0.3 m or more.^[8] Thus, hard setting can cause different problems at different depths. For example, when it occurs at the surface horizon, infiltration and aeration are reduced, and seedling emergence is inhibited (Fig. 1). When it occurs lower in the profile in the form of cohesive horizons, it causes problems of root elongation and water uptake.

The processes required for the formation of hard-setting surface horizons are: 1) slaking of aggregates under rapid wetting; and/or 2) dispersion of the clay fraction. Although the worst possible situation results when both slaking and dispersion occur, slaking or dispersion alone will result in a

Fig. 1 A silty loam surface soil that has hard set following irrigation. Note the problems of seedling emergence.

soil developing hard-setting properties. The soil mass consisting of these breakdown products then increases in strength as the soil dries. For the genesis of cohesive sub-soil horizons, evidence by Bezerra et al.^[7] suggests a combined action of poorly sorted sands and fine clay argilluviation is required. The role of siliceous and silico-aluminous compounds as temporary cementing agents in cohesive and hard-setting horizons also needs to be considered.^[9] These cementing agents further exacerbate the problem of hard setting. As they are important in the formation of hard-setting surface soils, the processes of slaking and dispersion are discussed here in detail. The interparticle bonding in hard-setting soils is also outlined.

Slaking Under Rapid Wetting by Irrigation or Rainfall

Under the forces involved in rapid wetting, soil aggregates may disintegrate into smaller particles called microaggregates.^[1] The extent of breakdown depends on how the strength of the aggregate can withstand the stresses due to rapid wetting. The stresses include swelling of the clays, compression of entrapped air, release of the heat of wetting, and the mechanical action of the wetting.^[10,11] Slaking is therefore affected by the amount and type of clay minerals, the organic matter content, the initial moisture content, and the rate of wetting.^[12] For example, silty surface horizons that are frequently cultivated are commonly low in organic matter. Under rapid wetting, they undergo severe slaking and result in hard-setting horizons. The hard-setting soil in Fig. 1 is typical of such a soil. It has a silty clay loam texture, organic carbon content of approximately 1.5%, and is used for row cropping.

Dispersion

Dispersion is the process whereby the microaggregates formed by slaking undergo further breakdown into

individual clay particles or packets of clay particles known as quasicrystals.^[13] The amount of dispersion depends on the exchangeable sodium percentage (ESP) of the soil, the total electrolyte concentration of the soil solution, and the amount of mechanical agitation the soil receives during wetting.

Interparticle Bonding in Hard-Setting Soils

The material produced by slaking of hard-setting soils consists of a mixture of sand grains and fragments of aggregated material as well as clay particles or packets of clay particles.^[12] In soils that have undergone both slaking and dispersion, the released clays bridge between the sand grains and fragments of disrupted material to form a dense, structureless mass. Greene, Eggleton, and Rengasamy^[14] demonstrated that when soils were sodium (Na^+) saturated, the extent of hard setting increased as the smectite content increased. However, when calcium (Ca^{2+}) saturated, hard setting decreased as the smectite content increased. The difference was because of the formation of quasicrystals in the Ca^{2+} system, which formed an open, less-dense structure with less hard-setting properties than a Na^+ system.^[13] With cohesive horizons, there is a significant reduction in void sizes and interconnecting pores compared to non-cohesive horizons. This poorly connected void network leads to higher values of bulk density and penetrometer resistance.^[7]

ASSESSMENT OF HARD-SETTING SOILS

It is important to be able to assess the likelihood of a soil to set hard in the field and to characterize the severity of that hard setting. Some of the measurements used are: 1) modulus of rupture (MOR); 2) tensile strength; 3) extent of slaking into microaggregates; and 4) amount of clay dispersion. The first two measurements involve strength measurements on reconstituted soil discs, while the latter two involve subjecting natural soil aggregates to wetting and characterizing the amount of structural disintegration into microaggregates and clay particles, respectively. Details of the four measurements are as follows.

MOR

Aylmore and Sills^[15] used a combination of MOR and hydraulic conductivity measurements to classify hard-setting sandy loam soils of the western Australian wheat belt. Soils were classified as hard setting if their MOR had a value of ≥ 60 kPa. Hard-setting soils also exhibited a more rapid increase in MOR with increasing ESP (sodium sensitivity) compared with non-hard-setting soils.

Tensile Strength

Tensile strength measurements on remoulded cores of soil are usually carried out after saturating the exchange complex of the soil with Na^+ . Greene, Eggleton, and Rengasamy^[14] used measurements of tensile strength to characterize the effect of clay content, cation exchange capacity, and clay type on the hard-setting properties of a range of hard-setting soils used for horticulture in the Carnarvon district of Western Australia.

Extent of Slaking (Wet Sieving Measurements)

Wet sieving techniques are used to measure the portion of soil aggregates that disintegrate on wetting due to slaking into microaggregates $<250\text{ }\mu\text{m}$ in size. These microaggregates are important in clogging interaggregate porosity and initiating problems of hard setting and crusting. As the extent of slaking depends upon conditions such as the initial aggregate size, moisture content, and rate of wetting, it is important to standardize these parameters in the test. It is also important to relate the size range of the products of aggregate disintegration formed by laboratory wet sieving procedures to actual processes of structural decline and soil strength development in the field.

Measurement of Soil Dispersion

Rengasamy et al.^[2] used measurements of clay dispersion to predict if a soil was likely to undergo surface crusting processes in the field. The test can also be used to predict the likelihood of a soil undergoing hard setting. Because clay dispersion was measured under different conditions, i.e., spontaneous and mechanical situations, it was also possible to use this test to predict the effects of different management procedures, e.g., tillage techniques and types of rotation, on soil behavior. The test was particularly useful in predicting the likely response of the soil to ameliorants such as gypsum and/or lime and to irrigation with different qualities of effluent.

MANAGEMENT

As rapid and prolonged wetting of air-dried cultivated soils leads to severe slaking and formation of hard-setting soils, any management techniques that avoid these practices will minimize structural breakdown and hence the extent of hard setting. Therefore, the use of surface mulches, low-application rate microirrigation, and raised beds, all of which slow the rate of wetting,^[12] is important.

Soil organic matter is critical in controlling the structural stability of a soil and hence its tendency to hard set. Tillage practices such as intensive, continuous

cropping lead to low soil organic matter concentrations and concomitant low structural stability. Therefore, pasture phases, which increase soil organic matter, are critical for the structural improvement of hard-setting soils.

Sodic soils, i.e., those containing a level of exchangeable $\text{Na} \geq 6\%$, are prone to dispersion and formation of crusting surfaces and hard-setting properties in the profile. The application of gypsum to dispersive, sodic soils, is a very efficient way of preventing dispersion and thus the problems of hard setting.

CONCLUSION

Hard setting is shown to be one of the most serious forms of soil structural decline that can occur. Its effects on a range of soil processes such as infiltration, emergence, air–gas exchange, and waterlogging are critical in determining plant performance and productivity. These potential limitations to productivity can be avoided only by correct assessment, followed by appropriate amelioration and management practices. Further work is urgently needed to develop an international system for classifying hard-setting soils.

Abstract

Historically, the “healthy soil–healthy people” concept made an important grassroots contribution to our reawakened interest in the key role that soil plays in the earth’s life-support system. Soil health may be viewed as the component of soil quality and ecosystem health that reflects the properties of soil as a living system. Although a healthy soil is an integral part of a healthy ecosystem, soil health plays a variable and sometimes negative role in soil quality, depending on the specific homocentric use of soil under consideration. The terms soil quality and soil health are converged but are not conceptually identical when the specific use of soil is to support ecosystem health.

SOIL HEALTH AND SOIL QUALITY

The terms soil health and soil quality have been used synonymously, at least from the standpoint that objective differences have not been clearly established.^[1–5] Soil quality is used almost exclusively by the scientific community, in part for brevity and in part because soil quality, concisely defined as “the degree of fitness of soil for a specific use” or “capacity of soil to function,”^[5–7] is felt to be less subjective, more quantifiable, and thus more defensible and less controversial than soil health (e.g., see Karlen et al.^[7]). In addition, integrating the concise and broader definitions of soil quality^[7,8] and the six landscape functions of soil^[9] identifies that soil quality is broader than soil health. Accordingly, for the three ecosystem functions, soil quality becomes the degree of fitness of soil to sustainably: 1) support biomass production and diversity; 2) protect environmental water and air quality by filtering, buffering, and transforming; and 3) maintain the earth’s genetic heritage; and, for the three “non-ecosystem” functions, soil quality is the degree of fitness of soil to act as sustainably as possible as a: 1) physical medium for infrastructures; 2) source of mining materials; and 3) keeper of the earth’s paleontological and our archeological heritage. The concept of soil health has little or no relevance to the three “non-ecosystem” functions, unless to rationalize a negative relationship between a healthy biologically active soil and the quality of soil to support these functions.

Despite the shift away from soil health to soil quality, there is general agreement that soil health appropriately conveys a more “soil as a living system” image as compared to the animate and/or inanimate “soil as a resource

for human development” focus of soil quality.^[2–7,9] Rather than force synonymy between soil health and soil quality, we suggest that soil health should be considered a component of soil quality that reflects the properties of soil as a living system and, within the context of ecosystem functions, can be defined separately as the degree of fitness of soil as a living system, within its natural means, to sustainably: 1) support biological production and promote plant and animal health; 2) maintain the earth’s genomic heritage; and 3) act as a living filter protector of water and air quality. The “within its natural means” qualification recognizes that the fitness of a soil to perform its ecosystem functions may be limited because of its inherent makeup, yet the soil may still be a resilient living system as long as it is managed within its capabilities. In practice, this definition of soil health converges with, but is not conceptually identical to, an exclusively ecosystem-based definition of soil quality.

SOIL HEALTH AND SOIL QUALITY WITHIN THE CONTEXT OF ECOSYSTEM HEALTH

Conflicts over the pros and cons of health as compared to quality concepts exist for managing rivers and watersheds as well as soil. In this regard, Karr and Chu^[10] persuasively rationalize that the concept of “ecological health,” as difficult as it is to define and measure, is an important policy goal with a greater opportunity to engage public support and interest than “ecological quality” because people more readily extend the idea of their own health to that of a watershed or ecosystem. As a component of ecosystem

health,^[11] soil health may be defined as the fitness of soil as a living system to sustainably help: 1) prevent ecosystem distress syndrome; 2) support ecosystem sustainability; and 3) protect the environmental quality of interfacing ecosystems. Ecosystem distress syndrome comprises a group of signs by which ecosystem breakdown is generally recognized, and for terrestrial ecosystems, it includes leaching of soil nutrients, reduced species diversity, shifts in species composition to opportunistic species, reduced productivity, and increased pest and disease loads.^[11] Fig. 1, with its

focus on the key role of soil as a biological reactor,^[13] illustrates the role of soil health in supporting biological production, biogeochemical cycling, energy flux, and environmental protection in an agroecosystem. For example, for a healthy soil: 1) agroecosystem distress syndrome is prevented by optimized biogeochemical cycling and a stable soil tilth restricting leaching and surface runoff loss; 2) agroecosystem sustainability is promoted by minimal external input of chemicals to the soil; and 3) the contamination of interfacing ecosystems is attenuated by the presence of

Fig. 1 Role of soil health in biomass production, biogeochemical cycling, energy flux, and environmental protection in an agricultural ecosystem. A Roman numeral above an element is the oxidation number of the element.

Source: Adapted from Romig, Garlynd, et al.^[12]

an effective living filter of soil and non-leakage of nutrients (such as nitrate) into groundwater by tightly coupled mineralization and plant root uptake. Similarly, contaminants entering the soil, either as a function of agronomic use or by accident, would ideally be integrated into the natural nutrient cycles and converted to harmless by-products for metabolism by soil organisms and higher plants (Fig. 1). Finally, it should be recognized that as a component of ecosystem health, soil health implicitly has built-in checks and balances. For example, because of its contribution to ecosystem distress syndrome and environmental contamination, rapid organic turnover and nitrogen mineralization resulting in soil organic matter depletion and excessive nitrate loss to the groundwater are not the characteristics of a healthy soil from an ecosystem health standpoint.

HOW DO YOU RECOGNIZE A HEALTHY SOIL?

As for other subsets of soil quality, the institutional approach to recognizing or assessing soil health involves describing each function on which soil health is to be based, selecting characteristics or properties that influence the capacity of the soil to carry out each function, choosing indicators of these characteristics, and using methods that can accurately measure these indicators.^[5]

Many of the results of the application of this approach to soil quality^[1-8] also apply to soil health and are not reviewed here.

Alternatively, building on tacit knowledge of how farmers recognize a healthy soil,^[1] a soil health scorecard was developed from structured interviews with Wisconsin farmers.^[12,14] The Wisconsin Soil Health Scorecard uses an ordinal, qualitative scoring mechanism for 43 soil health indicator properties to evaluate and monitor a soil's ability to support crop production. In addition to soil properties per se, farmers used plant, animal, human health, and to a lesser extent water properties to judge the health of their soils and relied heavily on sensory, descriptive criteria expressing how a healthy soil looked, felt, and smelled. Farmers commonly associated a sense of well-being and harmony with nature, with a healthy soil characterized by dark, rich earthy smelling humus, and friable, crumb structured soil tilth. However, it should be noted that the top 10 choices of farmers were more scientifically acceptable indicators of soil health, specifically, soil organic matter content, crop appearance, erosion, earthworms, drainage, tillage ease, soil structure, pH, soil nutrient test, and crop yield.^[12,14] The usefulness of integrating farmer-based, descriptive soil health indicators with analytical indicators in assessment of agroecosystem health remains to be seen.

Heat and Water Movement

Gerald N. Flerchinger

Northwest Watershed Research Center, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Boise, Idaho, U.S.A.

Abstract

The interrelation between heat and water flow in soil is complex. Temperature gradients can induce vapor and liquid water transfer within the soil; in turn, water movement carries heat with it, thus altering the thermal regime of soil. These interactions are often neglected to simplify analysis of thermal and/or moisture regimes of soil. However, many situations and processes require that soil heat and water flow be analyzed simultaneously. Soil freezing during cold season processes and water vapor movement in conjunction with soil surface evaporation are two examples where thermal and moisture processes are tightly linked and require simultaneous evaluation. These and other less obvious interrelations between soil heat and water are discussed.

THEORY OF SOIL HEAT AND WATER MOVEMENT

Temperature distribution in soil with provisions for water movement on heat transfer is given by the following equation:

$$C_s \frac{\partial T}{\partial t} - \rho_i L_f \frac{\partial \theta_i}{\partial t} = \frac{\partial}{\partial z} \left[k_s \frac{\partial T}{\partial z} \right] - \rho_l c_l \frac{\partial q_l T}{\partial z} - L_v \left(\frac{\partial q_v}{\partial z} + \frac{\partial \rho_v}{\partial t} \right) \quad (1)$$

The terms ($W m^{-3}$) represent, specific heat for change in energy stored due to a temperature increase; latent heat required to freeze water; net thermal conduction into a layer; net thermal advection into layer due to water flow; and net latent heat of evaporation within the soil layer, respectively. In Eq. 1, C_s and T are volumetric heat capacity ($J kg^{-1} C^{-1}$) and temperature (C) of the soil, respectively, t is time (s), ρ_i is density of ice ($kg m^{-3}$), L_f is latent heat of fusion required to freeze water ($J kg^{-1}$), θ_i is volumetric ice content ($m^3 m^{-3}$), z is depth within the soil (m), k_s is soil thermal conductivity ($W m^{-1} C^{-1}$), ρ_l is density of water ($kg m^{-3}$), c_l is specific heat capacity of water ($J kg^{-1} C^{-1}$), q_l is liquid water flow ($m s^{-1}$), L_v is latent heat of vaporization required to evaporate water ($J kg^{-1}$), q_v is water vapor transfer ($kg m^{-2} s^{-1}$), and ρ_v is vapor density ($kg m^{-3}$) within the soil. Three specific processes addressed by Eq. 1 in which heat and water movement are most closely coupled are soil freezing, water vapor movement, and thermal advection.

Soil Freezing

Due to negative water potentials, soil water exists in equilibrium with ice at temperatures below the normal freezing

point of bulk water and over the entire range of soil freezing temperatures normally encountered. When ice is present, soil water potential is a function of temperature.^[1] This relation is expressed as follows:

$$\phi = \pi + \psi = \frac{L_f}{g} \left(\frac{T}{T_K} \right) \quad (2)$$

where ϕ is total water potential (m), π is soil water osmotic potential (m), ψ is soil matric potential, g is acceleration of gravity ($m s^{-2}$), and T_K is absolute temperature (K). As temperature at the freezing front decreases, more and more water freezes, water potential becomes more negative, and liquid water content continues to drop, creating a gradient in water potential and liquid water content. This drop in liquid water content at the freezing front has a similar effect as drying of the soil, and water will migrate from moist regions to the freezing front. This often results in elevated ice contents, ice lenses, and frost heave.

Water Vapor Movement

Water vapor transfer can have a significant effect on the soil thermal environment due to the large latent heat of vaporization. Evaporation and subsequent vapor loss from the soil are very effective at cooling the soil. Vapor transfer in soil can be computed as the sum of flow due to a gradient in vapor density, q_{vp} , and that due to a temperature gradient, q_{vT} ,^[2] where:

$$q_v = q_{vp} + q_{vT} = -D_v \rho_v \frac{dh_r}{dz} - \zeta D_v h_r s \frac{dT}{dz} \quad (3)$$

Here D_v is vapor diffusivity ($m^2 s^{-1}$) in soil, h_r is relative humidity within the soil based on water potential, s is the slope of the saturated vapor pressure curve ($kg m^{-3} C^{-1}$),

and ζ is an enhancement factor. Observed vapor transfer in response to a temperature gradient exceeds that predicted by Eq. 3; therefore, an enhancement factor is included, which can vary from around 10 at high water contents to unity under very dry conditions.^[3]

Thermal Advection

As water moves through soil, it carries thermal energy with it. Liquid water moving from warm soil to relatively cooler soil will tend to increase the temperature of the cooler soil. The heat transported is based on heat capacity of water and is proportional to the liquid water flow, q_l , and temperature gradient, as expressed in Eq. 1. Under most conditions, water movement through soil is sufficiently slow that this term can be ignored.

Thermally Induced Liquid Flow

Variation in water surface tension with temperature and the heat of wetting can cause liquid flow in response to thermal gradients. Dependence of surface tension (or water potential) on temperature and the effect of thermal gradients on liquid water movement must be considered for non-isothermal conditions.^[4] As a result, the Richards' equation for water flow can become complex when generalized for non-isothermal conditions. Studies comparing simulations for surface soil evaporation with and without thermal effects show that liquid flow in response to thermal gradients accounted for only 1% of the evaporation.^[5] Thus, thermally induced liquid flow can usually be ignored.

EXAMPLES OF COUPLED HEAT AND WATER FLOW

Soil heat transfer due to soil freezing, water vapor transfer, and thermal advection is described by Eq. 1. The effects of these processes are illustrated using data collected in southwestern Idaho, U.S.A., and simulated by the Simultaneous Heat and Water model.^[6,7] The site had the following two soil types: a loamy sand and a silt loam.

Soil Freezing

The migration of water due to soil freezing is controlled primarily by the rate of freezing front advance in relation to the unsaturated hydraulic conductivity. With rapid soil freezing, soil water is essentially frozen in place, and there is little opportunity for water to migrate to the freezing front. Similarly, if the unsaturated conductivity is low, water migration to the freezing front will be slow. Thus, dry and/or coarse-textured soils exhibit much less frost-related water movement than moist, fine-textured soils.

Soil-water dynamics during soil freezing are illustrated for the silt loam soil in Fig. 1. For comparison, simulated

water content without considering freeze/thaw processes is also plotted. Elevated total water content due to water migration to the freezing front can be observed for all three depths, while the agreement between simulated and measured liquid water content was reasonable. Prior to day 344, simulated water content above 20 cm was decreasing due to drainage. After the initiation of soil freezing on day 344, the direction of flow reversed, and simulated water flow above 10 cm was upward toward the freezing front. As the 5-cm depth began to freeze on day 344, total water content began to increase, while simulated liquid water content continued to decrease. As the frost front advanced, the 5-cm total water content began to level off, and the 10-cm total water content began to level off, and the 10-cm total water content increased upon freezing on day 345. Subsequently, the 20-cm depth began to freeze on day 347.

Fig. 1 Simulated total water content and simulated and measured liquid water content for a silt loam soil for the 5-, 10-, and 20-cm depths. Also plotted is simulated water content without considering freezing dynamics.

Fig. 2 Simulated total water content and simulated and measured liquid water content for a loamy sand soil for the 5- and 10-cm depths. Also plotted is simulated water content without considering freezing dynamics.

Soil–water dynamics for the loamy sand were considerably less responsive to freeze/thaw processes than the silt loam (Fig. 2). Due to the low unsaturated conductivity of the loamy sand, the simulated increase in total water content was much smaller compared to the silt loam. Even so, total water content in the frozen layer increased gradually, while water content of the simulation which ignored freezing processes continued to drain.

Soil–water dynamics during freezing and thawing are critical to predicting frozen-soil-related runoff. Although not measured, simulated runoff for the silt loam and loamy sand were 16 and 13 mm, respectively; no runoff was simulated when freezing was not considered.

Ignoring freeze/thaw processes had a minor, but not insignificant, effect on simulated soil temperature. Compared to the full freeze/thaw simulation, ignoring effects of soil freezing resulted in simulated soil temperatures differing by typically 2.2°C for the 5- and 10-cm depths. Differences between the loamy sand simulations were somewhat less because there was less water to freeze.

Water Vapor Movement

Under moist conditions, vapor transfer within soil is usually negligible due to the lack of air-filled pore space.

Fig. 3 Measured 2-cm water content for a silt loam soil and simulated 2-cm water contents: 1) considering water vapor transfer; 2) assuming no water vapor transfer; and 3) neglecting the effect of thermal gradients on water vapor transfer.

However, under drier conditions, vapor transfer can significantly contribute to soil water movement and has a large effect on soil thermal conditions. Water vapor movement is especially important for a situation where the surface soil is dry and underlain by moist soil.

Measured 2-cm soil water content is shown in Fig. 3 along with simulated water content for three simulations as follows: vapor transfer included, vapor transfer ignored, and vapor transfer due to thermal gradients (q_{vT}) ignored. The simulation that ignored all water vapor transfer overestimated water content at the 2-cm depth because liquid flow through the dry ($<0.05 \text{ m}^3 \text{ m}^{-3}$) soil above 2 cm was insufficient to dry the soil beyond 1 cm. Conversely, the simulation which ignored thermal gradient vapor transfer, q_{vT} , overestimated water vapor transfer and therefore resulted in excessive water loss. Typically, daytime temperature gradients inhibit vapor movement toward the surface and reduce evaporation. Simulated evaporation for the 90-day period was 111 mm for the silt loam soil when vapor transfer was considered, 105 mm with no vapor transfer, and 117 mm when q_{vT} was ignored. Simulated evaporation for the loamy sand soil was 101, 96, and 105 mm, respectively.

Differences in evaporation between simulations had a moderate effect on simulated soil temperature. On average, the simulation without water vapor transfer had soil temperatures approximately 0.5°C warmer due to reduced evaporation. However, the absolute difference between simulations was as much as 1.2°C because ignoring vapor transfer caused higher temperatures during the day and cooler temperatures at night.

Thermal Advection

Heat transfer by soil–liquid water flow is usually quite small compared to thermal conduction. Average absolute

thermal gradient near the soil surface simulated for the bare soil plots was 1.6 C cm^{-1} . For typical values of thermal conductivity, it would require 1.3 mm hr^{-1} of liquid water flow (q_l) to transfer an equivalent amount of heat within a 1-cm layer. Thus, the effect of thermal advection of heat becomes important only for rapid infiltration of water. Indeed, one-year simulations neglecting the advection term during infiltration resulted in near-surface soil temperatures differing by typically $0.3\text{--}0.4^\circ\text{C}$ compared to simulations in which heat of advection during infiltration was considered. Maximum hourly differences of over 10°C occurred due to summer rainstorms on a hot soil surface (40°C). When advective heat transfer was considered during infiltration but ignored during redistribution, the temperature was typically within 0.03°C of the simulation considering advection. Thus, advective heat transfer can be significant during infiltration, but not generally important during the redistribution of soil water.

CONCLUSION

Interrelation between water and heat flow within the soil can influence the soil temperature regime. This influence is most pronounced in the case of soil freezing and thawing, and water vapor movement during surface evaporation. With the exception of rapid infiltration of water, heat carried by liquid water flow can usually be ignored. Thermally induced liquid water flow is usually insignificant.

From a practical standpoint, although water vapor movement influences evaporation from the soil and in turn affects water availability for plant growth, ignoring

this process usually provides evaporation estimates within 10% of actual values. Soil freezing, however, can significantly influence infiltration and runoff, causing severe flooding from relatively mild rainfall or snowmelt events.

Heat Capacity

Surinder Kumar Jalota

B.S. Ghuman

Department of Soils, Punjab Agricultural University, Ludhiana, India

Abstract

Soil temperature is an important edaphic factor. It plays a significant role in influencing soil microclimate which, in turn, affects seed germination, seedling emergence, and subsequent crop development. Changes in soil temperature are governed by its thermal properties, viz. conductivity, diffusivity, and heat capacity, in addition to solar radiation. Of these properties, heat capacity of soil is the one that controls temperature fluctuations to a larger extent and refers to the amount of heat existing in it. It is estimated from the mass or volume fractions and respective specific heats of different soil constituents such as minerals, organic matter, water content, and air. Soil and crop residue management practices such as tillage, compaction, puddling, and straw retention or removal from the field are commonly used for modifying heat capacity of the soil and thus its temperature.

HEAT CAPACITY

Heat capacity, also called thermal capacity, is not measured per se. It is measured by its effect on soil temperature. When heat is supplied, soil temperature increases, and when the heat is released, the temperature decreases. The ratio of heat supplied to a soil to its corresponding temperature rise is called the heat capacity, C , and is given by

$$C = \frac{Q_h}{\Delta T} \quad (1)$$

where Q_h is the quantity of heat supplied to soil in calories, and ΔT is an increase in its temperature in $^{\circ}\text{C}$.

Heat capacity of a soil can be expressed on mass basis (C_m) or volume basis (C_v). Heat capacity per unit mass of a substance, also called specific heat, is defined as the quantity of heat required to raise the temperature of 1 g of the substance by 1°C and is given by

$$C_m = \frac{\text{Heat capacity}}{\text{Mass}} = \frac{Q_h/\Delta T}{m} = \frac{Q_h}{m\Delta T} \quad (2)$$

$$Q_h = mC_m\Delta T \quad (3)$$

where C_m is the specific heat of the substance in $\text{cal g}^{-1}^{\circ}\text{C}^{-1}$, and m is the mass in g. Eq. 3 implies that the quantity of heat required to produce a given temperature change depends on the mass and the specific heat of the substance being heated. The heat capacities on mass basis or specific heats of soils, minerals, and some other materials are given in Table 1.

Specific heat affects soil temperature to a greater extent. Everything else being equal, a soil with a high mass heat capacity exhibits lesser temperature change than does one

having a low heat capacity. The presence of water in soil increases its heat capacity as heat capacity of water is 1.0 cal g^{-1} and that of many soil-forming minerals is nearly 0.2 cal g^{-1} . Therefore, moisture tends to buffer the soil against a very rapid change in temperature; e.g., heat capacity of dry soil is 0.2 cal g^{-1} , and if its moisture content is increased to 20%, the heat capacity of this soil would become 0.33 cal g^{-1} , and so on. It implies that more heat is required to warm a moist than a dry soil. Heat capacity on mass basis can be estimated from the following equation:

$$C_m = X_s C_s + X_w C_w + X_a C_a \quad (4)$$

where X_s , X_w , and X_a are mass fractions of soil solids, moisture, and air, respectively, and C_s , C_w , and C_a are their respective heat capacities.

In the soil physics literature, heat capacity on volume basis is a preferred term over mass basis. This is often known as volumetric heat capacity (C_v) and is defined as the quantity of heat required to raise the temperature of 1 cm^3 of soil by 1°C , and thus, its unit is $\text{cal cm}^{-3}^{\circ}\text{C}^{-1}$. For a dry soil, it is given by

$$C_v = D_b C_m \quad (5)$$

where D_b is the bulk density of soil in g cm^{-3} .

On volumetric basis, the heat capacity of a soil is expressed by De Vries^[10] as follows:

$$C_v = Y_s C_s + Y_w C_w + Y_a C_a \quad (6)$$

where Y_s , Y_w , and Y_a are the volume fractions of solid material, water, and air, respectively, and C_s , C_w , and C_a are their respective heat capacities. The contribution of the third term on the right-hand side of Eq. 6 to C_v is negligible

as compared to the other two terms and, therefore, can be neglected safely. The soil solid material is generally composed of soil minerals and organic matter. If the volume fractions of the soil minerals and organic matter are denoted

by Y_m and Y_o , respectively, and substitute the average value of heat capacity 0.46 for mineral constituents, 0.60 for organic matter, and 1.0 for water in Eq. 6, the heat capacity per unit volume of soil is given by

$$C_v = 0.46Y_m + 0.60Y_o + Y_w \quad (7)$$

In S.I. units, Eq. 7 can be written as follows:

$$C_v = 1.92Y_m + 2.51Y_o + 4.18Y_w \quad (8)$$

The unit of C_v becomes $\text{MJ m}^{-3} \text{K}^{-1}$.

By knowing the volume fractions of mineral matter, organic matter, and water content, one can obtain the heat capacity of soil from Eq. 7 or 8.

In the laboratory, heat capacity of soil can be determined by calorimeter method.^[11]

MANAGEMENT FACTORS AFFECTING HEAT CAPACITY OF SOIL

Heat capacity of soils is influenced by tillage, compaction, puddling, and mulching with crop residues. Higher volumetric heat capacity by $0.61 \text{ MJ m}^{-3} \text{K}^{-1}$ was reported in the top 15 cm layer of silt loam soil under no tillage than that under conventional tillage system ($2.05 \text{ MJ m}^{-3} \text{K}^{-1}$).^[12] Higher value of C_v in the no-till system relative to tilled was caused by increased aggregate stability, organic matter, and water storage capacity in the former system. Compaction improved the heat capacity of soils because of increased bulk density that resulted in more mass per cm^3 of soil.^[13] Mulching of soil with crop residue enhanced its heat capacity^[14] due to increased soil moisture content and organic matter. Puddling increased volumetric heat capacity of clay loam soil^[15] owing to increased moisture content though there was a decrease in bulk density.

CONCLUSION

In conclusion, heat capacity of soil, defined as the amount of heat existing in it, is affected by soil makeup and different soil and crop management practices. It is an important edaphic factor that affects seed germination, seedling establishment, plant growth, and yield. Value of heat capacity for a soil can be estimated from its mineral matter, organic matter, and water content. Heat capacity of a soil can also be measured in the laboratory.

Heat Flux

Thomas J. Sauer

National Soil Tilth Lab, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Ames, Iowa, U.S.A.

Abstract

The range of climatic conditions existing on the earth's land surface is related to physical position (elevation and latitude) and large-scale meteorological forces (such as ocean and air currents). Soil plays an integral role in influencing the climate near the ground. Properties of the soil surface affect the amount of sunlight energy reflected back to the atmosphere and the amount used to evaporate water, grow plants, warm the air above the ground, or warm the soil. The amount of thermal energy that moves through an area of soil in a length of time is referred to as the soil heat flux or heat flux density. *Soil heat flux* is a measure of the amount of energy moving into or out of the soil, which determines soil temperature and the rate of daily and seasonal temperature change. Soil temperature is one of the key factors in determining the rate of chemical and biological processes in the soil.

SOIL HEAT FLUX AND SURFACE ENERGY BALANCE

Early research on soil thermal regimes focused on soil temperature and its effects on crop growth.^[1,2] Soils subjected to different tillage practices or with contrasting physical properties were observed to warm at different rates in the spring. However, the processes controlling heat flow in soils were not adequately understood. Patten^[3] provided the first quantitative, comprehensive treatment of heat-transfer processes in soil by measuring the thermal properties of several soils under controlled laboratory conditions. By the mid-20th century, meteorologists became interested in measuring soil heat flux as a component of the surface energy balance:

$$R_n - G = LE + H \quad (1)$$

where R_n is the net radiation, G is the soil heat flux, LE is the latent heat flux, and H is the sensible heat flux (all in watts per square meter, $W\ m^{-2}$). *Net radiation* represents the net difference between incoming shortwave and longwave (thermal) radiation and reflected shortwave and terrestrial longwave radiation. *Latent heat flux* is the amount of energy consumed by evaporating water or released during dew formation. *Sensible heat flux* refers to the energy involved in heating or cooling the air layer near the soil surface.

The magnitude of G can vary, from near zero on a daily basis in temperate regions with dense crop cover, to 50% of hourly R_n in semiarid regions with no vegetation. Energy balance investigations^[4,5] have found complex interactions between atmospheric transport processes and soil thermal properties because both affect the dynamics of energy flow

in surface soil layers. Fig. 1 presents an example of diurnal patterns of energy balance terms at a pasture site in northwestern Arkansas. These data are for two days in autumn (October) when the soil was moist and the grass canopy was 0.35 m tall. The sum of G for both days was negative (i.e., the soil was cooling) and equivalent to less than 1% of the magnitude of the daily R_n .

FACTORS AFFECTING SOIL HEAT FLUX

The partitioning of R_n at the soil surface and the soil thermal properties influences diurnal and annual patterns of soil heat flux and determines the ability of the soil to transfer energy to and from the surface. The amount of reflected shortwave radiation, which depends on soil color, soil wetness, surface cover, and surface roughness, is one component of the partitioning of R_n at the surface. In general, plants or plant residues reflect more shortwave radiation than do bare soils. Smooth surfaces with lighter colored or dry soils also tend to reflect more shortwave radiation than do uneven surfaces with dark-colored or wet soils. Surface roughness and soil wetness also affect LE and H in that roughness enhances turbulent mixing of the air near the surface and the availability of soil water affects evaporation.

Soil heat capacity and thermal conductivity are the key thermal properties affecting soil heat flux.^[6] The heat capacity of a soil is the amount of energy (MJ) required to change the temperature of a volume of soil (m^3) $1^\circ K$. A soil's thermal conductivity is the constant of proportionality relating the temperature gradient across the soil to the soil heat flux, as defined by Fourier's equation:

Fig. 1 Energy balance components for a pasture site in north-western Arkansas for two days in October 1997.

$$G = -k \, dT/dz \quad (2)$$

where k is the thermal conductivity ($\text{W m}^{-1} \text{K}^{-1}$), T is the soil temperature (K), and z is the distance between the soil temperature measurements (m). Table 1 lists typical heat capacity and thermal conductivity values for different soils and soil constituents. Because of the much greater (approximately 3500 times) heat capacity of water as compared with air (4.18 vs. $0.0012 \text{ MJ m}^{-3} \text{K}^{-1}$), a moist soil has a much higher heat capacity than a dry one. However, the thermal conductivity of water is approximately 23 times greater than air (0.57 vs. $0.025 \text{ W m}^{-1} \text{K}^{-1}$). Thus, a moist soil conducts heat more efficiently than a dry one, but it takes much more energy to develop the same temperature gradient in a moist soil as compared with a dry one.

In field settings, G can be limited by the ability of the soil to conduct heat or by the amount of available energy at the surface. Soil heat flux measured over a 24-hour period at a depth of 0.05 m in a no-till corn field in central Iowa in fall, winter, and spring is presented in Fig. 2. In fall, the fresh corn residue effectively insulated the dry

Fig. 2 Seasonal variation in soil heat flux at 0.05 m in a no-till corn field in central Iowa.

soil from solar radiation inputs. In winter, a layer of snow 0.23 m thick covered the wet residue and soil. Because of the insulating effect of the snow layer, the soil heat flux remained negative (i.e., the soil was slowly losing heat to the atmosphere) and showed little diurnal trend. By spring, the increase in decayed residue exposed more of the wet soil to incoming radiation, causing the peak soil heat flux to nearly double that of the peak measured during the fall.

MEASUREMENT TECHNIQUES

Because soil heat flux is such an important parameter in agrometeorology and soil science research, several measurement methods have been developed.^[9,10] The choice of a specific method depends on the intended use of the data, the resources available, and the degree of accuracy required. One category of techniques uses measured and/or estimated soil thermal properties combined with soil heat flow theory to estimate G . These techniques, which include calorimetric, gradient, and combination, generally require numerous and accurate measurements of soil temperature, heat capacity, and thermal conductivity at various depths in the soil. Depending on the accuracy desired, some or all of these parameters must be measured at several locations, at frequent intervals, and for each depth throughout the measurement period. Such requirements make their use relatively tedious and time consuming. The second category uses a sensor, called a heat flux plate or heat flow transducer, designed specifically to measure soil heat flux. Soil heat flux plates are small (often <50 mm per side), thin (<5 mm thick), rigid sensors placed horizontally in the soil. Most employ a thermopile located inside a waterproof housing to measure the temperature difference between the top and bottom of the plate. Temperature difference across the plate is used to estimate heat flux through the soil. Although this technique is much simpler to use, the plate itself can disturb soil heat and water flow, thereby reducing accuracy in some situations. Corrections

Table 1 Observed thermal properties of various moist soils and soil components at ambient temperatures.

Material	Heat capacity ($\text{MJ m}^{-3} \text{K}^{-1}$)	Thermal conductivity ($\text{W m}^{-1} \text{K}^{-1}$)

must be made for heat storage in the soil above the plate in order to calculate G at the soil surface accurately.

CONCLUSION

The rates of chemical and biological processes in soil are strongly affected by temperature. Soil heat flux, the amount of heat moving into or out of the soil, can be altered to optimize the soil thermal environment. Irrigation, drainage, tillage, and crop residue management can all be used to affect energy transfer at the soil surface by modifying the surface characteristics and soil thermal properties. Knowledge of the factors affecting soil heat flux is essential for optimizing plant growth through modification of the soil thermal regime and microclimate near the ground.

Heavy Metals

Mike J. McLaughlin

Land and Water, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Glen Osmond, South Australia, Australia

Abstract

Some heavy metals are essential for either plant or animal survival on land, while others are non-essential and toxic at low concentrations. This entry reviews heavy metals, their abundance, and their biological effects.

INTRODUCTION

It is generally accepted that metals having a specific gravity (weight per unit volume) greater than 5 Mg m^{-3} are termed heavy metals. In soils, these elements include cadmium (Cd), cobalt (Co), chromium (Cr), copper (Cu), iron (Fe), mercury (Hg), manganese (Mn), molybdenum (Mo), nickel (Ni), lead (Pb), and zinc (Zn).^[1] The term “heavy metals” is often used synonymously with the term “trace elements,” but this is incorrect as trace elements are generally defined as those elements normally occurring in soil at concentrations less than 100 mg kg^{-1} ,^[2] which precludes several heavy metals, e.g., Cr, Fe, and Mn. Arsenic (As) is often included in the group “heavy metals” but is more correctly classified as a metalloid.

GENERAL CHEMISTRY

Some heavy metals are essential for either plant or animal survival on land (Co, Cr, Cu, Fe, Mn, Mo, Ni, and Zn), while others are non-essential and toxic at low concentrations (Cd, Hg, and Pb). All the heavy metals, except Pb, are transition elements, belonging to the d-block in the periodic table. Many of these elements differ from the alkaline earth metals (e.g., Na, Ca, and Mg) in that they can exist in several valence states in soil (Table 1). In particular, Cr, Fe, and Mn are markedly affected by soil redox potential and undergo both oxidation and reduction depending on soil conditions. This has important implications for the availability and toxicity of many heavy metals. As both Fe and Mn are major structural metals in soil minerals, reduction of the Fe^{3+} and Mn^{4+} ions may lead to a change in soil mineral surfaces important for retention of many elements, including other metals. For Cr, oxidation converts the non-toxic Cr^{3+} ion to the toxic and carcinogenic Cr^{6+} ion. This reaction has even more significance in soils as a strongly sorbed or precipitated cation (Cr^{3+}) is converted into a poorly sorbed or soluble anion (CrO_4^{2-}).

However, even in aerobic soils, Cr^{3+} is the thermodynamically stable state, so added Cr^{6+} ion is rapidly converted to Cr^{3+} in most soils.

Solubility and availability/toxicity to organisms of heavy metal cations (Cd^{2+} , Cr^{3+} , Fe^{n+} , Pb^{2+} , Mn^{n+} , Hg^{2+} , Ni^{2+} , and Zn^{2+}) decrease as soil pH increases. This is due to the increase in negative charge on variable charge surfaces in soil^[4] and the propensity for these metals to precipitate as sparingly soluble compounds (phosphates, carbonates, and hydroxides), as soil pH increases.^[5] On the other hand, solubility and availability/toxicity to organisms of anionic heavy metals (CrO_4^{2-} and MoO_4^{2-}) may increase as soil pH increases, again due to increases in surface negative charge on soil particles affecting sorption. Under reducing conditions in soil, many of the metals form insoluble metal sulfides, therefore reducing availability to plants and animals.

Heavy metals are also subjected to complexation reactions in soil with both inorganic and organic ligands, which may markedly increase mobility in soil. This may be used to good effect by plants in scavenging essential metals from soil, e.g., phytochelatins (see below). However, for non-essential metals, complexation and increased mobility also may lead to increased environmental risks through leaching and plant uptake, e.g., chloride-induced uptake of Cd by food crops in saline soils.^[6]

ABUNDANCE IN ROCKS AND SOILS

Heavy metals become incorporated into primary minerals in igneous rocks through isomorphous substitution. In sedimentary rocks, heavy metals are incorporated as constituents of minerals, or are removed from the water column and trapped in sediments by adsorption or precipitation processes.^[7] Apart from Cr, Fe, and Mn, heavy metals are generally present at trace concentrations ($<100 \text{ mg kg}^{-1}$) in most soils, with the exception of soils developed over mineralized parent materials or soils developed through biological enrichment.^[8] Background concentrations in soil

usually reflect the composition of the parent rock material. Background concentrations of heavy metals are usually determined where no known anthropogenic inputs have occurred, but this assessment is often problematic due to the global spread of anthropogenic emissions through atmospheric transport processes.^[9] The typical range in abundances of heavy metals in unpolluted soils is shown in Fig. 1.

Concentrations of heavy metals in soil can be significantly increased through human activity. A number of primary and secondary sources have been identified as contributing to enhanced concentrations of heavy metals in soil^[12] (Table 2). Many countries have introduced legislation to minimize the amount of metals accumulating in soil and set ceiling concentrations above which further metal additions must stop.

BIOLOGICAL EFFECTS

Co, Cr, Cu, Fe, Mn, Mo, Ni, and Zn are all essential for either healthy plant or animal functioning in soil and all these metals, except Ni, are used in fertilizers or animal stock supplements to ensure efficient agricultural production on soils deficient in essential metals. Due to the low solubility of essential heavy metals in neutral and alkaline soils, many plants have developed strategies to mobilize solid phase forms to facilitate uptake by roots (e.g., Fe, Mn, and Zn). Non-proteinogenic amino acids,

Table 2 Sources of heavy metal contamination in soils.

Source	Main heavy metals
Primary sources	
Fertilizers	Cd, Cu, Mo, Pb, Zn
Irrigation water	Cd, Fe
Manures and composts	Cd, Cr, Cu, Fe, Hg, Mn, Mo, Ni, Pb, Zn
Pesticides	Cu, Hg, Pb, Zn
Sewage biosolids (sludges)	Cd, Cr, Cu, Fe, Hg, Mn, Mo, Ni, Pb, Zn
Soil amendments (lime, gypsum, etc.)	Cu, Mn, Pb, Zn
Secondary sources	
Automobile Aerosols	Pb
Coal combustion	Pb
Mine waste and effluents	Cd, Cu, Fe, Hg, Mn, Ni, Pb, Zn
Nonferrous smelter waste	Cd, Cu, Hg, Mn, Ni, Pb, Zn
Paint dispersal	Cd, Pb
Tire wear	Cd, Zn
Waste combustion	Cd, Pb

Source: Adapted from Barry & Rayment.^[8]

or phytochelatins, secreted by actively growing roots are important in acquisition of Cu, Fe, Zn, and possibly Mn from deficient soils.^[13] At high concentrations in soil, all the essential elements may pose risks to microorganisms, plants, animals, or humans (Fig. 2). Non-essential heavy metals in soil (Cd, Hg, and Pb) have no beneficial effects at low concentrations (Fig. 2) and may be toxic at even trace concentrations (e.g., Cd and Hg).

Critical exposure pathways for expression of heavy metal toxicity in soil have been examined as part of regulation governing reuse of biosolids (sewage sludge) on soil^[14] but act as a general risk analysis template for all types of pollution of soil by heavy metals.^[15] For some elements, e.g., Cd and Co, food chain transfer is the main risk pathway, as these elements are easily accumulated by plants in edible tissues. For other elements, sorption in soil

Fig. 2 Typical concentration–response relationship for (A) essential and (B) non-essential heavy metals in soil.

Table 3 Critical risk pathway assessments for heavy metal pollution of soils.

Metal	Dominant risk pathway	Secondary risk pathway	Most important predictor required
Cd	Food chain transfer	Phyto- and ecotoxicity	Soil–plant uptake
Co	Food chain transfer	Phyto- and ecotoxicity	Soil–plant uptake
Cr	Phyto- and ecotoxicity	Metal leaching	Toxic threshold definition, speciation
Cu	Phyto- and ecotoxicity	Soil ingestion by animals/humans	Toxic threshold definition
Fe	Phyto- and ecotoxicity ^a	None	Toxic threshold definition
Hg	Soil ingestion by animals/humans	Metal leaching	Toxic threshold definition, speciation
Mn	Phyto- and ecotoxicity	Soil ingestion by animals/humans	Toxic threshold definition
Ni	Phyto- and ecotoxicity	Soil ingestion by animals/humans	Toxic threshold definition
Pb	Soil ingestion by animals/humans	Phyto- and ecotoxicity	Oral bioavailability assessment
Zn	Phyto- and ecotoxicity	Food chain transfer	Soil–plant uptake

^aOnly in acid soils under reducing condition.

is strong, bioaccumulation by microorganisms low, and plant uptake and translocation so low that the dominant risk pathway is (for higher animals and humans) through direct ingestion of soil, e.g., Hg and Pb. For the other heavy metals, behavior in soil and bioaccumulation characteristics result in toxicity to plants and microorganisms (phyto- and ecotoxicity) being the dominant risk pathway at high concentrations, e.g., Cr, Cu, Mn, Ni, and Zn. Thus, prediction of risks from heavy metal pollution of soils through soil testing requires a different emphasis depending on the metal considered (Table 3).

History of Soil Science

Eric C. Brevik

Department of Natural Sciences, Dickinson State University, Dickinson, North Dakota, U.S.A.

Artemi Cerdà

Department of Geography, University of Valencia, València, Spain

Abstract

Human knowledge of soil has come a long way since agriculture began about 9,000 B.C.E., when finding the best soils to grow crops in was largely based on a trial and error approach. Many innovations to manage and conserve soil, such as the plow, irrigation techniques, terraces, contour tillage, and even the engineering of artificial soils, were developed between 9,000 B.C.E. and 1,500 C.E. Scientific methods began to be employed in the study of soils during the Renaissance and many famous scientists addressed soil issues but soil science did not evolve into an independent scientific field of study until the 1880s. In the early days of the study of soil as a science, soil survey activities provided one of the major means of advancing the field. As the 20th century progressed, advances in soil biology, chemistry, genesis, management, and physics allowed the use of soil information to expand beyond agriculture to environmental issues, human health, land use planning, and many other areas. The development of soil history as a subfield of the discipline in the latter part of the 20th century has promise to help advance soil science through a better understanding of how we have arrived at the major theories that shape the modern study of soil science.

INTRODUCTION

It is important for soil scientists to study the history of our field. A true understanding of the hypotheses and theories that shape the way we approach the modern study of soils can only be appreciated if we also understand where they came from and what other possibilities have been explored. This facilitates understanding the strengths and weaknesses of our knowledge base and in developing a core understanding of our discipline. Studying history can also assist in directing research away from routes that are likely to be unfruitful as well as point us in directions that have not been well explored previously and may have promise for additional research. Understanding soil science history from an international perspective can help improve communication between countries, avoid wasted effort through the exploration of ideas already established elsewhere, and perhaps more importantly, can assist in forming a common language among soil scientists. Knowing our history can make us more efficient and effective as scientists.

Soil science history has become a fairly well-established subfield in modern soil science. Professional societies including the European Geosciences Union (EGU), International Union of Soil Sciences (IUSS), and Soil Science Society of America (SSSA) have established subdivisions or committees within their structures that promote the study of soil science history. In addition, many leading soil science journals will accept soil science history submissions,

and several internationally known soil scientists and historians have contributed to our understanding of the field's history.

ANCIENT SOIL SCIENCE (9000 B.C.E. TO 1500 C.E.)

Through much of history soil knowledge has been linked to agriculture. The earliest evidence of agricultural activity, including manipulation of soil to promote crop growth, comes from a site near Jarmo, Iraq.^[1] However, agriculture also developed in areas beyond the Middle East. Africa, China, and Peru and Mexico in the Americas saw the development of societies that cropped their own cereals, tubers, or vegetables. Animals were domesticated, which changed soils due to grazing and the manuring of exhausted soils, reducing the use of shifting agricultural practices and encouraging sedentary societies and increasingly intensive use of soil resources.^[2] The development of agriculture independently in different parts of the world explains the high biodiversity of agricultural crops, and human reliance on agriculture transformed the soils of the world in a few millennia.^[2] Except for Antarctica, agriculture, including grazing, is widespread over all the continents of the world. A number of management advances were made over the next several thousand years, including the development of early plows, terracing, and contour tillage,^[1] all designed to improve soil conditions for the purpose of crop production.

Fig. 1 Intercropped maize and squash with ground cover in a traditional Wampanoag garden at Plimoth Plantation, Massachusetts. Note in particular the small mounds at the base of each maize plant, showing the planting of the maize in individual hills.
Source: Photograph by Eric Brevik.

During this time, humans also began to recognize spatial patterns in soil and settlement patterns in many regions began to correlate to soil types.^[3] By 2000 B.C.E., the Chinese had developed a soil classification system, as did the Greeks by about 300 B.C.E.^[1] Advances were also made in the Americas. The Aztec, Inca, and Maya in Central and South America constructed artificial soils to improve crop production and developed bench terraces; these civilizations were among the most successful in human history at minimizing soil erosion and creating sustainable agricultural systems.^[1] In a sense they originated the concept of soil conservation. Native Americans in North America were cultivating crops by 5000 B.C.E. and maintained soil fertility using intercropping of diverse crop mixes, adding ash from burned weeds and trees, and incorporating fallow periods.^[4] Crops were typically planted in small mounds (Fig. 1), which were more resistant to erosion than the rows that were traditional in Europe.^[4]

SCIENCE IS APPLIED TO THE STUDY OF SOIL (1500 C.E. TO 1880 C.E.)

The Renaissance began in the western world about 1500 C.E., and scientific practice in western societies was revolutionized. Scientific methodology began to be applied to the investigation of a number of phenomena, and scientists who are well known for their contributions to other fields applied scientific principles to the study of soil. For example, Charles Darwin, famous for the theory of evolution, worked on the concept of soil profiles and through his study of the influence of earthworms on soil formation became a leading figure in establishing soil biology^[1] while Leonardo da Vinci, Francis Bacon, and Robert Boyle, widely regarded as a founder of modern chemistry,

conducted early studies in nutrient cycling in and plant nutrition from soil.^[5] By the late 1820s, C. Sprengel proposed a theory on mineral nutrition of plants and the law of the minimum that would become the basis of J. von Liebig's "Mineral Theory" of plant nutrition, which is well known to soil scientists.^[6]

During this period, governments in Europe became interested in land valuation as a basis for taxation, which led to creation of the first soil maps in the early 1700s. The Chinese had also used soil attributes as a basis for taxation as early as the 1100s but did not create soil maps to assist in this.^[5] As more accurate and detailed base maps became widely available in many parts of Europe in the 1800s, thematic maps such as soil maps could be made much more efficiently and accurately.^[7] This led to a significant expansion of soil mapping efforts in Europe and the United States.^[1,5]

Despite the application of scientific principles to soil science issues during this time, the study of soil science as a scientific field had not developed. From 1500 C.E. to 1880 C.E., soils were being investigated as components of chemical, geological, or biological systems but were not viewed as an independent field of study in and of themselves. Events that occurred in the 1880s would change that view.

SOIL SCIENCE DEVELOPS AS AN INDEPENDENT SCIENTIFIC FIELD (1880 C.E. TO 2000 C.E.)

The early 1880s were marked by the 1883 publication of "Russian Chernozem" by Vasilii V. Dokuchaev, an event that is widely recognized as the birth of modern soil science.^[1,5,8] In this work and others, Dokuchaev: 1) recognized soil as an independent natural body worthy of study in its own right; 2) established the five soil forming factors that are widely used and developed one of the first models of soil genesis; and 3) broadly introduced the concept of A, B, and C horizons as they are used today.^[1,8,9] Although Dokuchaev certainly did not do all of this on his own, and aspects of his ideas had been discussed previously by other scientists, Dokuchaev was able to pull all the ideas together and present them in a logical and convincing fashion to a scientific world that was largely ready to accept them,^[5] even if it would take decades before some parts of the world would do so.^[1]

The end of the 1800s and beginning of the 1900s also saw the beginning of detailed national soil survey programs in many countries (Table 1).^[8] These surveys became significant drivers in the development of soil science knowledge, as soil surveyors sought to understand the genesis and function of the soils they discovered as well as develop classification systems to organize this new knowledge. Initially, these surveys tended to be focused on soil knowledge as needed for agriculture, but over time the role of these surveys expanded to include information

Table 1 The beginning date for detailed nationally organized soil survey for select countries.

relevant to geomorphology studies, land use planning, paleoenvironmental reconstructions, archaeology, human health, soil and water conservation, and other environmental issues.^[8] The use of soil information to address environmental issues was probably the fastest growing non-agricultural area of soil science in the second half of the 20th century.^[11] Early soil surveyors used paper maps and then aerial photographs as base maps, but by the end of the 20th century, remote and proximal sensed imagery managed with geographic information systems (GIS) was available that significantly advanced the information available to map soils and investigate spatial variability. These new data sources and tools also challenged traditional concepts of map scale.^[7]

By the early 1900s, there was considerable interest in the links between soils and human health. In Europe, Robert McCarrison, the County Palatine of Chester Local Medical and Panel Committee, Lady Eve Balfour, and André Voisin were all early voices promoting soil and human health links, while in the U.S. individuals such as Charles E. Kellogg, Selman Waksman (who was awarded the 1952 Nobel Prize in Physiology or Medicine for the isolation of antibiotics from soil microorganisms), William Albrecht, and J. I. Rodale investigated the issue.^[10] Sir Albert Howard, well-known worldwide for his work promoting organic agriculture, was a major proponent of the idea that soils were intimately linked to human health. In the latter part of the 20th century, a wide array of soil and human health topics were studied, including exposure to heavy metals, organic chemicals, and pathogens, the filtration capacity of soils, nutrient supply through the soil–plant system, and the supply of medications (about 40% of all prescription drugs have a soil origin). By the end of the 20th century, much had been learned about links between soils and human health, but there was a need for well-designed scientific studies.^[10]

Selected individuals, such as M.E. Wöllny in Germany^[1] and William John McGee and Edward Elway Free in the United States,^[4] studied soil erosion in the late 1800s and early 1900s, but few people viewed soil erosion as a serious problem until the Dust Bowl hit the United States in the

1930s.^[11] A combination of the Dust Bowl and persistent preaching of the erosion problem by Hugh H. Bennett led to the formation of the Soil Erosion Service (SES) by President F.D. Roosevelt in 1933, which was transformed into the Soil Conservation Service (SCS; now the Natural Resources Conservation Service) by an act of Congress in 1935.^[1] Both the SES and the SCS were under Bennett's direction. The SES/SCS undertook a number of soil erosion projects to test and demonstrate soil conservation and erosion control measures; one of the major results of these efforts was the development of conservation tillage.^[4] These projects were also interdisciplinary and transdisciplinary, including agronomists, anthropologists, biologists, engineers, economists, and soil scientists.^[4] The idea that interdisciplinary and transdisciplinary studies are critical to the advancement of soil science is quite popular,^[8,11] but the SES/SCS projects show that this is not a new idea. Despite the fact that soil erosion studies received a lot of attention in the United States beginning in the 1930s, by the end of the 20th century the United States was the only country in the world that had long-term soil erosion data collected using standardized methods for large expanses of the country. Other countries either did not have standardized data collection in place or waited until much later in the 20th century to begin national programs of erosion data collection and assessment.^[12] While erosion data were available for much of the rest of the world, coverage was more sporadic than in the United States and methods were not as standardized.^[12]

In the latter half of the 20th century, soil science history began to develop as a subfield of the discipline. Most who work in this subfield have their primary specialization in one of the scientific subfields of soil science or in a subfield of history but devote some of their time to soil science history because they feel it is important. Many well-respected soil scientists, including but certainly not limited to Ronald Amundson, Winfried Blum, James Bockheim, Johan Bouma, Marlin Cline, Christian Feller, Walter H. Gardner, Alfred Hartemink, Daniel Hillel, Hans Jenny, Rattan Lal, Alex McBratney, Daniel deB. Richter, Roy Simonson, Johan Six, Donald Sparks, and Dan Yaalon have published on various aspects of soil science history, and there has been a concerted effort by the soil scientists in the soil history community to reach out to like-minded historians for collaborations. Historians who have engaged in these collaborations include Lloyd Ackert, Benjamin Cohen, John McNeill, Martin Melosi, Laura Sayre, Richard Unger, and Verena Winiwarter.^[13] The study of soil science history received a major boost in 1982 when IUSS Commission 4.5—History, philosophy, and sociology of soil science was created, largely due to the efforts of Dan Yaalon.^[13] SSSA formed the Council on History, Philosophy, and Sociology of Soil Science in 1990 to coordinate with IUSS activities in this area with leadership from John Tandarich, Walter Gardner, Chris Johannsen, and Roy Simonson.^[13] The most recent professional scientific society to add soil science history to regular society activities was EGU. This

began in 2011, when Artemi Cerdà, the president of the Soil Systems Sciences (SSS) Division of EGU at the time, contacted Eric Brevik and Alfred Hartemink with a request to organize a soil science history session for the 2012 EGU General Assembly (GA). At the 2012 EGU-GA, the History, Education, and Society of Soil Science subdivision was created during a reorganization of the SSS.^[13]

CURRENT STATUS (2000 C.E. TO 2015 C.E.)

Through history soil science has made great strides as a scientific field, particularly during the latter parts of the 19th century and the 20th century. Information learned and soil maps generated have proven highly valuable in addressing many modern issues from agriculture to the environment, human health, and beyond. However, there were plenty of challenges for soil scientists to address as we transitioned from the 20th century to the 21st century. Soil survey coverage is very good in some countries but is largely lacking in others,^[12] and even countries that have nearly complete soil survey coverage lack the quantitative, georeferenced soil information that is needed as input into modern high tech computer models.^[8] There are many different soil classification systems, which make it difficult to communicate soil information internationally, so a common language would help.^[8] The new high-powered computers, global positioning systems, GIS, proximal and remote sensing information, and advanced spatial statistical and numerical analysis techniques available to soil scientists make a wealth of information available, but better models are needed to tie all the available information together and take full advantage of it.^[8,12] There is also a need for interdisciplinary and transdisciplinary collaborations that will bring new ability and insights into the work we do, enhancing the value of the final products produced for all end users.^[8,11] These challenges should not be viewed as problems or weaknesses but rather as challenges that continue to make the field of soil science vibrant, exciting, and needed in the modern world.

CONCLUSION

Studying the history of our field provides insights into how we arrived at modern understandings and the strengths and weaknesses inherent in that understanding. It also has the ability to point out potentially promising new areas of study by identifying areas that have not received adequate attention, and it has the ability to identify past directions of study that were not fruitful. This entry is only a very brief summary of major points in soil science history, and there is much more to be explored. Publications presented in the references and bibliography can provide a large amount of additional information that this entry did not have the space to address.

History of Soil Science: 1927–2000

Fred P. Miller

School of Natural Resources, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

In 1927, the First International Congress of Soil Science was convened. By this time, soil science fragmented, multidisciplinary origins had begun to coalesce through national and international conferences the formation of scientific societies and institutional organization of its subject matter. Soil science is positioned to attain both recognition and legitimacy within the scientific community as a natural science discipline. Soil plays a major role in accommodating and driving fundamental ecological processes. It is the planetary medium in which our human sustenance is literally rooted, upon which much of civilization's activities take place, and through which most of society's waste loads are disposed of and recycled.

INTRODUCTION

The year 1927 serves as a logical divide between the early history of soil science and its 20th century counterpart. That year, the First International Congress of Soil Science was convened in Washington, D.C. By this time, soil science fragmented, multidisciplinary origins had begun to coalesce through national and international conferences the formation of scientific societies and institutional organization of its subject matter; e.g., in 1924, the International Society of Soil Science had been founded in Rome, linking the major subdisciplines of soil science (soil physics; soil chemistry; soil biology; and soil genesis, classification, and cartography, collectively known as pedology) in a single, structured international organization.^[1] Pedology was seen as an independent subdiscipline of soil science no longer tethered to its more narrowly focused mother discipline of geology.^[1–8]

While chemistry (including mineralogy), physics, and biology (microbiology) constitute major pillars upon which the discipline of soil science was founded and rests, the segment of soil science known as pedology consists of a hard core of science unique to soil science and that has no place in other more basic sciences.^[7] Pedology, therefore, constitutes the fourth pillar of the discipline of soil science—the study of the origin of soils (soil genesis), their morphology, and the relationship of soils to landscapes and ecosystems.

DEVELOPMENT OF SOIL SCIENCE IN THE UNITED STATES

The First Half of the 20th Century

In another article, John Tandarich has set forth the early history of soil science, including the development of soil

science in the United States up to 1927. During the first half of the 20th century, soil science and its literature in the United States were heavily influenced by the soil survey program, eventually called the National Cooperative Soil Survey of the United States.^[9–11]

In 1920, those working in the soil survey program organized themselves into the American Association of Soil Survey Workers, later known as the American Soil Survey Association in 1923. It was the American Soil Survey Association that sponsored the First International Congress of Soil Science in 1927 in Washington, D.C. In 1936, this association merged with the soil section of the American Society of Agronomy, which was founded in 1907, to form the Soil Science Society of America (SSSA). Although this merger was not without detractors in the soil survey program, it did unite the various sub disciplines of soil science [soil physics, soil chemistry (including mineralogy and fertility), soil biology–microbiology, and pedology] under a single professional–scientific society. As recorded in an increasing literature about soil science, much progress had been made in soil physics, chemistry, mineralogy, and microbiology by this time.^[5,6,10]

After 1929, the Great Depression coupled with the Dust Bowl of the 1930s stimulated demand for soil information in general and soil survey information in particular. Soil erosion had long been the Achilles heel of American agriculture. More information about the problem was needed by farmers and land managers to manage land better and minimize the ecological scourges of land and soil degradation. Economic conditions coupled with drought and erosion in America's heartland during the early 1930s prompted the Roosevelt administration to form the Soil Erosion Service in 1933, later restructured into the Soil Conservation Service in 1935. After a rocky fiscal start, the soil survey program was a major component underpinning these agencies' missions.^[9]

In 15 years preceding his death in 1935, Curtis F. Marbut, the American pioneer of pedology, devoted himself to developing a comprehensive natural system for classifying all known soils.^[9] Marbut's final soil classification system (1935) was revised in 1938 by his successor, Dr Charles E. Kellogg, and published in the 1938 Yearbook of Agriculture.^[12] This classification system was again revised in 1949 and published in the journal *Soil Science* as a special issue.^[13]

At the same time, the other subdivisions of soil science were making advances. Likewise, refinements in soil classification continued, and soil mapping was greatly enhanced by the introduction of aerial photography. Although the feasibility of mapping on air photos was well established by 1929, aerial photo base maps did not come into general use in soil surveys until several years later.^[9] In 1937, Kellogg issued the first Soil Survey Manual,^[14] setting forth guidelines, standards, and techniques for soil surveys.

Midway through the 20th century, the major paradigms of soil science had been established. These included:

- The pedogenesis concepts of Dokuchaev–Hilgard (vs. the earlier geology-based concepts of soil formation), refined by Marbut, Jenny, Cline, Simonson, and others.^[1,2,5,6,9,11,15]
- The chemical basis of plant nutrition, begun by Sprengel and von Liebig in Germany in the mid-1800s (vs. earlier focus on humus as the essence of soil)^[1,6] and essential concepts such as the chemistry of ion exchange, solute transport, and colloidal chemical phenomena.^[5,6]
- The theoretical basis of soil physics, such as soil hydraulic conductivity (Darcy in 1856) and soil mechanics (Terzaghi in the 1920s and the 1930s).^[1,5]
- The understanding and characterization of soil mineralogy, particularly clay mineralogy (with the advent of X-ray techniques and thermic analysis) and its roles in soil chemical phenomena and the physical behavior of soils.^[6]
- The basis of soil microbiology and the role microorganisms play in nitrification and the cycling of elements and compounds, the practical relationship of soil microbiology to plant growth, the decomposition of plant residues, the character and dynamics of humus, and an inventory of microbial species in the soil and the study of their roles.^[1,5,6]

As Boulaine^[6] noted, the end of World War II and the close of the first half of the 20th century brought much attention to the need for soil science, including “the expansion of irrigation, the conquest of newly cultivated land, attempts at rehabilitating salty soils, the drainage of marshes, and the fight against erosion requiring technical inventories, periodic surveillance, and predictions concerning the eventual evolution of the land. These needs had repercussions on

research programs and on ways of defining pedological variables.” Boulaine concluded that “a remarkable flowering of soil science” marked the next half century to follow.^[6]

The Second Half of the 20th Century

McDonald^[16] noted that the year 1950 is a logical starting point for an analysis of modern trends in soil science and its literature. In 1949, the first *Advances in Agronomy* had been issued under the auspices of the American Society of Agronomy and included a number of articles concerning soils. In 1951, the revised and expanded *Soil Survey Manual* was published.^[16,17] This book refined the standardization of soil survey procedures and guidelines as well as established the primary functions of the United States soil survey program.^[9] Research on soils was taking place in many areas; e.g., in 1952, Selman A. Waksman, a microbiologist–biochemist at Rutgers University, received a Nobel Prize for his discovery and isolation of the soil microbe streptomycin.^[1,5,6]

The year 1950 also marked the beginning of an effort to develop an entirely new natural system for classifying the known soils of the world. Since 1938 major revision of the U.S. classification system^[12] and its less intensive revision in 1949,^[13] expanded knowledge of soils, more intensive demands on the use of soils, and new and broader applications of soil surveys could no longer be reconciled with the established soil classification schemes of 1938 and 1949.^[9,18] Guy D. Smith, coauthor of the 1949 revision^[13] and a soil scientist in the United States Division of Soil Survey, assumed leadership of this international effort to develop a new comprehensive system of soil classification.^[9]

This project resulted in the publication of *Soil Taxonomy* in 1975.^[18,19] Subsequently, international committees were established by the U.S. National Cooperative Soil Survey to work on problems and concerns arising from the use of *Soil Taxonomy*.^[8] Revisions of this work resulted in further refinement of this new classification system with the world's soil resources classified into 12 major global soil orders. The lowest level in the classification system, with the most narrowly prescribed ranges of soil properties, is known as the soil series. In the United States, there are more than 14,000 established soil series, a 24-fold increase in the eighty-year period between 1912 and 1992. By the end of 1992, virtually all arable land in the United States had been classified and mapped under the mandates of the Food Security Act of 1985.^[18]

Advances in technology including isotopic tracers, computers, satellites, fractal mathematics, geo-statistics, and biotechnology have rapidly been applied to many areas of soil science. Computers and sophisticated software have allowed complex soil system behavior to be modeled. The remote sensing of landscapes via satellites and rapidly processed information contributed to the development of

sophisticated geographic information systems that provide soil scientists with powerful tools to investigate spatial soil relationships as well as predict soil behavior under various ecosystem manipulations. Biotechnology provides tools for assessing, understanding, and manipulating the soil microbes that drive many soil and ecological processes. These and many other opportunities for soil science research have been reviewed.^[20]

In the 1960s and 1970s, agricultural interests emphasized economic and resource efficiency in production. During the same period, the environmental movement became more influential. Soil scientists and their colleagues in agronomy, engineering, forestry, range management, and other scientific areas began to research not only the cropping system responses to production inputs and ecosystem manipulations, but also their environmental impacts. Both interest in and demand for such research, coupled with available funding, drove the research agenda, as reflected in the literature published during this time in the mainline soil science journals (*Journal of Environmental Quality*, *Soil Science Society of America Journal*, *Agronomy Journal*, and *Soil Science*).

The discipline of soil science, particularly pedology, has also had significant influence on American assessments of land and water resources inventories during the 20th century. After Bennett's first comprehensive soil erosion inventory in 1934,^[21] a soil-and-water conservation needs inventory was conducted and published in 1945.^[22] Later inventories of the nation's soil and water resources were conducted using scientific and statistically reliable protocols. A series of conservation needs inventories were carried out between 1958 and 1967.^[23,24] Subsequent inventories of the condition of the nation's land and water resources, known as the National Resource Inventories (NRI), were completed in response to the requirements of the Rural Development Act of 1972 and the Soil and Water Resources Conservation Act of 1977 (RCA). The first RCA appraisal^[25] was conducted in 1977. The second and more comprehensive RCA–NRI appraisal^[26] reported conditions for the nation's land for 1982. The 1987, 1992, and 1997 (revised in 2000) NRI updates have been completed^[27–29] and provide information to guide policy formulation in managing and sustaining the nation's natural resources.

During the 1990s, the discipline of soil science focused on a variety of agricultural and non-agricultural problems and issues. An assessment of the literature of soil science as it pertains to these issues can be found in McDonald.^[30] Soil scientists in the 1990s assessed soils as ecosystem components and concentrated on processes that drive ecosystem functions. Several references for this entry provide examples of the research initiatives of the 1990s, including isotopic signatures in soil development, computer-assisted tomography, thermo-mechanical processes in soils, fractal mathematics and chaotic flow analytical methodologies, aqueous and surface chemical speciation, microbial habitat assessment and genetic characterization of soil microbes,

and extraterrestrial pedology.^[20,31–35] The number of issues and problems addressed by American soil scientists is also illustrated by the topics presented at the 2000 annual meeting of the SSSA. These topics and issues contrast sharply with the subjects addressed by soil scientists years ago because of scientific advances during this time coupled with society's demands for stewarding the nation's natural resources. These topics include:

- ecosystem manipulation and response to mitigation strategies;
- capacity of soils and the environment for food production;
- carbon sequestration potential of managed soil-cropping systems;
- remediation of contaminated soils and landscapes;
- indicators of soil and environmental quality;
- sustaining ecological integrity under high-output agriculture;
- computer modeling and computer-assisted decision making; and
- riparian buffer management as a water quality protection practice.

THE STATUS OF SOIL SCIENCE AS A DISCIPLINE IN 2000

Born from the basic and natural science disciplines, but nurtured throughout the 20th century by agricultural institutions (U.S. land grant colleges and the U.S. Department of Agriculture agencies, such as the Soil Conservation Service/Natural Resources Conservation Service and the Agricultural Research Service), soil science seeks professional–scientific parity with its earth science and natural science counterparts.^[36,37] Soil science is perceived by many to be an agriculturally oriented discipline. But since World War II, and particularly since the 1970s and 1980s, soil science research and its applications have been broadened well beyond the boundaries of agriculture. Evidence of the discipline's growth as a bona fide earth science and natural science discipline includes:

- greater identity of the SSSA from its long professional partnership with the American Society of Agronomy and the Crop Science Society of America;
- SSSA's membership in the American Geological Institute;
- publication of soil science research in international science journals such as *Science*, *Nature*, and others;
- research addressing global, national, regional, and local issues in both agricultural and non-agricultural domains;
- soil scientists becoming members of the U.S. National Academy of Science and other prestigious science-oriented affiliations and awards;

- collaboration in interdisciplinary research;
- successfully competing for research grants;
- membership on political boards, advisory panels, and other political organizations guiding public policy;
- long history of international exposure and participation; and
- contributions to state-of-the-art research on a natural resource critical to the sustenance of humankind and its well-being.

CONCLUSION

At the threshold of the 21st century, soil science is positioned to attain both recognition and legitimacy within the scientific community as a natural science discipline. Soil plays a major role in accommodating and driving fundamental ecological processes. It is the planetary medium in which our human sustenance is literally rooted, upon which much of civilization's activities take place, and through which most of society's waste loads are disposed of and recycled. To paraphrase Boulaine's observation in the mid-20th century,^[6] the "flowering of soil science" should continue into the 21st century.

History of Soil Science: Early to Mid-20th Century

John P. Tandarich

Hey and Associates, Inc., Chicago, Illinois, U.S.A.

Abstract

This entry briefly traces the development of soil science in the western world from its origins in Greek thought, evolving as a separate agricultural interest of classical chemistry and classical mineralogy. The agricultural interests crystallized as agricultural chemistry and agricultural geology. The science evolved from the mid-19th century from the interactions with other disciplines, principally, chemistry and geology.

INTRODUCTION

Soil science is the scientific study of soil as a unique independent phenomenon of nature, in all its complex interrelationships. The interrelationships of soil are those interactions of physical, chemical, biological, geological, geomorphological, climatological, and temporal factors that are combined to create the soil and are responsible for the geographical arrangement of soil on the shallow water-scapes and landscapes of the earth.

The historiography of soil science has been increasing since the late-20th century. Some of the works are by Boulaine,^[1,2] Jenny,^[3] Krupenikov,^[4] Simonson,^[5] Strzemeski,^[6] Tandarich,^[7–11] Warkentin,^[12] and Yaalon.^[13]

This entry ends at 1927 when the First International Congress of Soil Science was held. Miller treats soil science history subsequent to this point.

AGRICULTURAL CHEMISTRY

In the Greek world, it was Empedocles of Agrigentum who proposed four elements as the basis for all existence, namely: earth, air, fire, and water. These four elements of Empedocles, developed and refined by Aristotle, became the accepted “Classical Model” for almost 2000 years.^[14] The Classical Model of the four fundamental elements was the basis for understanding the physical world from the 8th through the 14th centuries, when knowledge centers were within monastery walls and courts of royalty. The rediscovery of the ancient Greek and Roman philosophers by Renaissance Scholars in monasteries and newly established universities revitalized scientific inquisitiveness and allowed progress in knowledge to move forward in the 15th and 16th centuries.^[10]

By the late 17th century, the Royal Society of London, and particularly Robert Boyle, recognized the agricultural value of the knowledge of soil types, their properties, and condition.^[15] Simultaneously, northern European chemists

were also analyzing and classifying soils; prominent among these were Johann Becher and his student Georg Stahl and Johann Wallerius and his student Count Gustavus Adolphus Gyllenborg.^[14] By the late 18th century, Scottish chemist Joseph Black had analyzed and classified calcareous marls.

With the rise in France of the new experimental chemistry of Antoine Lavoisier in the late 18th and early 19th centuries, scientists in many countries became involved in soil analyses, particularly focused on the organic matter component; that for them was the soil. Some of these individuals were Jean Chaptal and Jean-Baptiste Boussingault in France; Humphry Davy in England; and Albrecht Thaer, Heinrich Einhof, and their student Carl Sprengel; Jons Berzelius and his students Heinrich Rose, Eilhard Mitscherlich, and Gerardus Mulder; and Gustav Schubler in Northern Europe.^[10,14]

Scientists in Northern Europe were particularly active. In 1837, Sprengel^[16] first used the term *Bodenkunde* (soil knowledge) in his text. At the same time, Justus von Liebig, his colleagues, and his students initiated an academic tradition that continued to the early 20th century and produced many agricultural chemists.^[14] Many of these scientists were also outstanding teachers, such as Pieter Muller, Emil Ramann, Hermann Stremme, and Georg Wiegner and his student Hans Jenny in Europe; Joseph H. Gilbert in England; Alexandr Khodnev, Pavel Ilienkov, Alexandr Voskresenskii, and his student Dmitri Mendeleev, and Nikolai Zinin and his student Alexandr Butlerov in Russia; and Eben Horsford, Eugene Hilgard, John Norton, William H. Brewer, Samuel W. Johnson, and George Caldwell in the United States.^[10,14,17,18]

AGRICULTURAL GEOLOGY

Simultaneously with the development of agricultural chemistry, knowledge of soils was accumulating, expressed within what would be called geology and geography. In the

late 17th and early 18th centuries, Royal Society of London members Martin Lister, John Aubrey, and William Stukeley proposed that soils be analyzed and mapped. The 1684 work by Lister^[19] included the first soil classification scheme. In 1743, Christopher Packe^[20] published a large-scale physiographic and soils map of East Kent, England. Pioneer soil mapping of the late 18th and early 19th centuries in Great Britain and Ireland culminated in a series of county-based agricultural surveys, called “General Views of Agriculture” made for the British Board of Agriculture under the leadership of Arthur Young.^[21]

By the end of the 18th century, a renewed interest in soils developed from a redefinition of classical mineralogy by German classical mineralogist Abraham Werner into Geognosie (geognosy—eventually replaced by the name geology), Oryctognosie (modern mineralogy), and Mineral Geography.^[22,23] Geognosie was defined as “the abstract systematic knowledge of the solid earth.”^[22] That part of geognosy regarding the earth’s surface, and as applied to agriculture, was spread through Werner’s students. Werner’s student Alexander von Humboldt and his student and colleague Carl Ritter spread new geographic and cartographic methods and techniques through Europe and Russia. They influenced their academic colleagues and successors and government officials to adopt these new methods and ideas. Some of the inspired in Northern Europe were Friedrich Fallou, who coined the name Pedologie in 1862 to represent the true science of the soil elevated from Sprengel’s soil knowledge;^[24] and Albert Orth,^[25,26] who developed the soil profile concept; Alexandre Brongniart, Georges Cuvier, and his Swiss student Louis Agassiz in France; and members of the Imperial Free Economic Society of St. Petersburg in Russia such as Vasilii Dokuchaev.

In Scotland, Robert Jameson’s interpretation of that part of geognosy concerned with the earth’s surface influenced William Maclure. In the early 19th century, Maclure brought this knowledge, much of which would become known as agricultural geology, to Benjamin Silliman and his students and academic successors in the United States; some of whom were Amos Eaton, Edward Hitchcock, Ebenezer Emmons, David Dale Owen, George H. Cook, Nathaniel Shaler, William Morris Davis, Alexander Winchell, Eugene Hilgard, Thomas Chamberlin, W.J. McGee, Frank Leverett, and Curtis F. Marbut.^[7–9,11] The agricultural geologists’ concept of soil focused on soil as separate formation in its own right deserving of study.^[27] This discipline became concerned with processes leading to soil formation, such as the weathering of rocks and minerals, and how these processes influenced soil fertility.

Practicing agricultural geologists (or agrogeologists as they called themselves by the turn of the 20th century) began meeting in 1909.^[28] Van Baren^[29] summarized the state of the science of agrogeology in an introduction to a comprehensive bibliographic work on the subject by Wulff.^[30] The agricultural geology, or agrogeology, period lasted until the 1920s.^[11,13]

THE EMERGENCE OF SOIL SCIENCE

When did modern soil science emerge from agricultural chemistry and agricultural geology? It appears that the emergence took place during the period from 1837 to 1927, and particularly after 1860, as shown by the indicators that Greene^[31] proposed: 1) the establishment of major organizations representing soil science; 2) review articles and bibliographies published; and 3) textbooks published on the subject.

Rossiter^[17] forcefully argued that agricultural chemistry was already accepted, taught, and practiced in the United States by the mid-19th century. Simultaneously, agricultural geology was already establishing itself in Europe and the United States with its own literature.^[11,30] Modern soil science developed from agricultural chemistry and agricultural geology through a complex series of interactions among individual scholars; academic and governmental institutions; and scientific societies of England and Scotland, France, Denmark, Germany, Hungary, Romania, Sweden, Russia, and the United States.

Many of the major organizations representing soil science were created during the early 20th century: the American Society of Agronomy (ASA), Soils Section in 1908; the International Conferences on Agrogeology in 1909 that became the International Society of Soil Science (ISSS) in 1924;^[28] and the American Association of Soil Survey Workers in 1920 that became the American Soil Survey Association in 1922. Between 1924 and 1927, the ISSS created an organizational structure that recognized commissions (soil science subdisciplines) of soil physics, soil chemistry, soil bacteriology (biology), nomenclature, classification and cartography (what is known as pedology), soil fertility, and soil technology.^[13]

Greene^[31] noted that the appearance of historical review articles of disciplines indicates that the particular discipline is in a transitional or significant developmental state. In Russia, Dokuchaev^[32] reviewed the literature on soils in 1879. There were review articles and bibliographies on soils published immediately after the formation of the ASA,^[33,34] prior to the establishment of the ISSS,^[29,30] and in conjunction with the First International Congress of Soil Science.^[35]

Textbooks on soil science began to appear in Europe and Russia beginning in the early to mid-19th century.^[2,12,14,17,36] Briefly, some of the principal works were by Sprengel,^[16] Fallou,^[24] Orth,^[25,26] and Dokuchaev,^[32,37,38] and Dokuchaev’s student Konstantin Glinka^[39] brought the Russian ideas to the West with the assistance of Hermann Stremme and Marbut.^[40]

In England, significant publications included those by John Bennett Lawes and Joseph Henry Gilbert, who pioneered in soil fertility research at the Rothamsted Experiment Station, Lawes established in 1843,^[41,42] and by Arthur Hall^[43] and Edward J. Russell.^[44] In Germany, the

books of Emil Ramann,^[45,46] who originated forest soil science, and Hermann Stremme^[47] built upon the work of Fallou and Orth.

Significant books on soils in the United States began with Nathaniel Shaler's^[48,49] in the early 1890s. Others that followed included those by Franklin King^[50] in soil physics, Hilgard,^[51] Milton Whitney,^[52] Thomas L. Lyon, Elmer Fippin, and Harry Buckman,^[53] George Coffey,^[54] Marbut et al.,^[55] Lyon,^[56] and Lyon and Buckman^[57] that has gone through 11 editions.

The First International Congress of Soil Science was held in the United States in Washington, D.C., in 1927 and brought together scientists from the Eastern and Western worlds and from all subdisciplines of soil science for meetings and a transcontinental field trip.^[58] This meeting effectively launched modern soil science. Miller treats the history of soil science from this turning point.

Deborah A. Kozlowski

Edenton, North Carolina, U.S.A.

Abstract

Histosols differ from other soils in that organic materials dominate. They form in wet anaerobic environments from the bottom-up rather than from the top-down. The utility of Histosols extends beyond agriculture and horticulture to a source of renewable fuel and waste treatment. The potential hazards of fire, subsidence, and building/construction difficulties can be overcome with proper management. Histosols in their natural state may be home to rare plants and animals and provide a unique environment for all.

INTRODUCTION

Definition

Soil Taxonomy^[1] defines Histosols as soils composed primarily of organic matter (OM). The amount of OM [in terms of organic carbon (OC)] needed to classify any soil as organic varies depending on the clay content of the sample (Fig. 1). It should be noted that even at high (60%) clay contents, the amount of OC needed to classify material as organic is only 18% by weight; thus, 82% of the remaining matter will be inorganic mineral material. Therefore, one should consider a Histosol not only in terms of the actual amount of organic material, but also in terms of how the organic materials dominate the soil properties.

The name Histosol has its roots in Greek *histos* for tissue and Latin *solum* for soil; thus, Histosol is “tissue soil.” The source of the tissue is the deposition and subsequent decomposition by products of both plants and animals. The deposited tissues are the parent materials. For the formation of Histosol, the rate of decomposition must be slower than the rate of deposition, resulting in an accumulation of organic material (Fig. 2).

Distribution

Histosols can be found worldwide in areas where OM is accumulating (Table 1).^[2,3] These generally are areas where the OM is deposited in saturated and anaerobic environments such as wetlands. They may occur in cold climates where decomposition is slowed down due to lower temperature and biological activity or wherever decomposition is slow.

Histosols can be divided into three groups.^[2,4] First are those that form due to landscape position in depressional areas, seeps, marshes, or where surface flow causes saturated and anaerobic conditions. These can occur in any climatic setting. Second are those formed on flat topography where annual precipitation exceeds annual evapotranspiration. Pocosins, blanket peats, and raised bogs are typical of this group.^[5–7] Third are the Histosols on mountains where extremely shallow soils are composed only of plant material. These may not remain saturated and anaerobic for extended periods, but accumulate OM due to reduced biological activity.^[2–4]

Description

Describing Histosols involves methods beyond those used for describing mineral soils. Organic horizons are described for color (wet and dry if possible), structure, consistency, reaction, roots, pores, additional features, and boundary just as mineral soils. Fiber content (excluding living roots and material <2 mm in size) is also estimated, first by observing a freshly broken face, then by rubbing the sample 10 times between thumb and forefinger and by determining the amount of fibers remaining. Both rubbed and unrubbed colors are determined.^[1,4]

All horizons considered OM based on OC content are designated as O horizons. Further divisions are based on the degree of decomposition represented in the horizon: Oi (fibric or peat) the least decomposed; Oe (hemic or mucky peat) of intermediate decomposition; and Oa (sapric or muck) the most decomposed. Peat material has > 75% fibers, muck peat has between 75% and 17% fibers, and muck has < 17% fibers remaining after rubbing.^[1]

Fig. 1 Relationship between OC and clay content in order for a horizon to be considered organic.

FORMATION

In mineral soils, the least weathered or pedogenically altered material is the C horizon material, which is farthest from the surface. Organic soils are just the opposite. In order to understand this, consider that the freshly deposited litter is C horizon or parent material from which the Histosol

Fig. 2 Photograph of the Pungo series. This is an undrained profile located in Washington Co., North Carolina, U.S.A. Note the visible fibers near the surface and the decrease in their amount with depth. Also note the large wood fragment preserved in the profile. The scale is metric.

developed. The litter falls on the surface of the soil, buries the decomposing OM from previous years, and begins to decompose. The bottom consists of the most decomposed material, and the top is the least decomposed.

Factors governing decomposition are temperature, moisture content, type of OM, pH, microbial activity, and time.^[4] The decomposition process must be slow enough to allow the net accumulation of OM. Saturation is one way to assure this, as high OM contents rapidly lead to anaerobic conditions. Anaerobic microbial decay is significantly slower than aerobic decay, allowing OM to accumulate. Decomposition rates also slow down as temperature drops; however, lower temperatures alone may not result in OM accumulation; in most cases, anaerobic conditions must occur still.

Ripening or aerobic breakdown may occur when organic soils are drained (Fig. 3). Ripening results in increased decomposition and overall loss in volume of the Histosol.^[8,9] Limiting the depth of drainage can control the degree of this subsidence, but if accumulation rates drop below decomposition rate, a volume decrease is inevitable. Ripening may result in the formation of strong structural units in the OM, greatly improving the hydraulic conductivity.^[7,10]

PROPERTIES

The physical and chemical properties of Histosols are related to OM content.^[4] Histosols have bulk densities below 1.0 Mg m^{-3} , but vary with the type of OM involved and mineral content. As the OM content increases, bulk density generally decreases, and as the degree of decomposition increases, bulk density increases.^[3,11] Histosols also have high *in situ* moisture contents and moisture-holding capacity because they are formed under wet conditions and have a low bulk density. The high water-holding capacity does not necessarily result in a high hydraulic conductivity as some have K_{sat} values less than those in clay soils, while others are too rapid to measure.^[7,12] The high moisture

Fig. 3 Photograph of the Scuppernong series. This is a drained profile located in Hyde Co., North Carolina, U.S.A. Note the darker surface caused by the ripening of the surface due to drainage. The scale is in inches.

Source: Photo by J.A. Gagnon, Jr., USDA-NRCS.

content results in significant shrinkage upon drying. The low bulk density and high moisture content give Histosols low bearing capacity.

As the high OM content accounts for low bulk density, it also accounts for a high cation exchange capacity (CEC), which can easily exceed $100 \text{ cmol } 100 \text{ g}^{-1}$.^[13] As the OM decomposes, more functional groups associated with the organic compounds are exposed; thus, CEC will increase with greater decomposition.

USES AND PROBLEMS

Histosols have many uses including crop production, horticultural products, fuel, and waste treatment. In their natural state, Histosols are utilized as wildlife refuges and are recognized for their aesthetic charm. They serve as a repository for paleoclimatic and anthropologic information.

Crop production is perhaps the most common commercial use of Histosols. Low bulk density makes the soils ideal

for root crops but presents problems with management.^[7,13] For equipment to traverse the low bulk density material, the soils must be drained. Once drained, the rate of decomposition increases. Management of the water table must achieve a balance among subsidence, trafficability, and plant growth. Drainage is also needed to allow proper rooting depths of crops and assure proper surface drainage. The result may be a complex management plan that includes ditches to lower the water table and improve surface drainage. The drained Histosol decomposes, releasing nutrients, but the amount released will not sustain a viable agronomic crop. Soil testing of organic soils is critical to meet the macronutrient and micronutrient needs. The lack of micronutrients in organic soils, copper in particular, was not fully understood.^[7] Once adequate levels of micronutrients were added, productivity on some organic soils exceeded that of mineral soils. Another challenge with organic soils is maintaining a proper pH. Target pH on acidic organic soils is typically lower than that on mineral soils.^[7]

Histosols are the major source of organic soil amendments such as peat moss. The material may be extracted by vacuuming the dry material off the surface or by scraping a thin surface layer off and stockpiling it until dry. Some peat resources, if managed appropriately, will heal; thus, they are considered a renewable resource.^[14]

The idea of organic soils as a renewable resource is appealing when considering its use as a fuel. Russia and Ireland have vast peat reserves and use them as fuel for heating and generating electricity. On a dry weight basis in British thermal units, organic soil falls between wood and lignite.

The high surface area and CEC of Histosols make them ideal for waste treatment.^[15] Organic material from Histosols can be used as an air filter. Sewage can be treated using peat materials both *in situ* and in specially constructed peat filters. These filters have been used to treat wastewater generated from single-family homes commonly removing 95% of the fecal coliform, 90–95% of the biochemical oxygen demand (BOD), and 95% of the total suspended solid (TSS) (Table 2, Fig. 4).^[16] Working with Histosols

Table 2 Average treatment results from four peat biofilter systems in North Carolina.

	Untreated waste water effluent	Peat biofilter effluent (treated effluent)	% change
Fecal Coliform (cfu/100 ml)	2×10^5	1.1×10^3	–99
BOD ₅ (mg L ^{–1})	143	5	–96
TSS (mg L ^{–1})	116	6	–95
Total Kjeldahl nitrogen	27.5	3	–90
NH ₄ –N	20.3	0.9	–96
NO ₃ –N	0.4	20.1	+98

Source: From Lindbo & MacConnell.^[16]

does present problems such as increased fire hazard, subsidence, building and construction difficulties, and the possibility of corrosion to metal and concrete. Fire hazards are greatly increased when the soils are drained or during extreme dry periods.^[9] Once fire starts, it is extremely difficult to extinguish it and may burn deeply into the soil for months or longer until the water table rises to douse the fire.^[7]

Subsidence begins as soon as decomposition exceeds accumulation. Typically, this occurs with drainage. In cropped areas, the surfaces fall gradually. Subsidence can cause roadways to buckle or washboard if support techniques or removal of the organic material is not done appropriately. Buildings may end up “floating” precariously as the ground surface drops.

Beyond subsidence, in construction, the low strength of the material also poses a challenge. Vehicles working on Histosols need to have low bearing weights in order to avoid sinking in the muck. Prior to the use of large equipment on Histosols, plow animals may be equipped with special bog shoes to prevent them from sinking. The low pH of Histosols may cause corrosion; therefore, metal or concrete requires prophylactic treatment.

CONCLUSION

Histosols differ from other soils in that organic materials dominate. They form in wet anaerobic environments from the bottom-up rather than from the top-down. As long as enough water is present to slow the decomposition rate below the rate of accumulation, Histosols may form. The high OM content in Histosols accounts for

their low bulk density, low strength, high surface area, and high CEC. These properties not only lead to high crop productivity, but also lead to increased management concerns involving drainage, macro- and micronutrient needs, and trafficability. The utility of Histosols extends beyond agriculture and horticulture to a source of renewable fuel and waste treatment. The potential hazards of fire, subsidence, and building/construction difficulties can be overcome with proper management. Finally, Histosols in their natural state may be home to rare plants and animals and provide a unique environment for all.

Human Culture and Soils

Daniel Hillel

Center for Climate Systems Research, Columbia University, New York,
New York, U.S.A.

Abstract

For at least 90% of its existence as a species, the human animal functioned merely as one member of a community of numerous species who shared the same environment. Early humans were adapted to subsist within the bounds defined by the natural ecosystem. By and large, our ancestors led a nomadic life, roaming in small bands, foraging wherever they could find food. They were gatherers, scavengers, and opportunistic hunters. Unlike their primate cousins who remained primarily vegetarian, humans diversified their diet to include the flesh of whichever animals they could find or catch, as well as a variety of plant products such as nuts, berries and other fruits, seeds, some succulent leaves, bulbs, tubers, and fleshy roots.

INTRODUCTION

Our *species*' birthplace was evidently in the continent of Africa, and the original habitat was probably the sub-tropical savannas that constitute the transition zone of sparsely wooded grasslands lying between the zone of the humid and dense tropical forests and the zone of the arid steppes. We can infer the warm climate of our place of origin from the fact that we are naturally so scantily clad, or furless, and we can infer the open landscape from the way we are conditioned to walk, run, and gaze over long distances.

EARLY DEVELOPMENT

Some hundreds of thousands of years ago, members of the *Homo* genus learned to fashion stone tools as well as to set and use fire, probably at first only to cook and soften food. Later, they used fire to clear woody vegetation, to flush out game, and to encourage the subsequent grazing of ungulates, which they could thereby hunt more readily. Eventually, that practice had a great effect on the environment, as brush fires apparently set by humans modified entire ecosystems on an increasing scale. The control of fire became even more important when humans moved out of the tropics into colder climes, where bonfires and hearths were needed to warm their shelters in winter as well as to cook their food. In time, the clearing of woodlands and shrublands by repeated firings also set the stage for the advent of agriculture. However, as the vegetative cover is affected by fire, so is the underlying soil. Following repeated denudations of the land, soil organic matter and nutrients were gradually depleted, while soil erosion took place,

resulting in the increased transport of silt by streams and its deposition in river valleys and estuaries.

By the later stages of the so-called Paleolithic period, nearly all the regions of human habitation had experienced some anthropogenic modification of the floral and faunal communities. The gradual increase in human population density required the development of more intensive methods of land use, aimed at inducing an area to yield a greater supply of human needs. The selective eradication of less desirable plant and animal species and the encouragement of desirable ones (producing edible and, preferably, storable products) led eventually to the domestication and propagation of crops and to purposeful soil management aimed at creating favorable conditions for production. That is to say that these activities culminated in the development of agriculture and the sedentary (rather than nomadic) way of life in regular villages.

THE AGRICULTURAL TRANSFORMATION

Concurrently with the domestication of plants, humans also learned to select and domesticate animals. The earliest domesticates in the ancient Near East were sheep, goats, and bovine cattle, which could be herded and pastured in the semiarid rangelands. Cattle (oxen) were also used as beasts of burden to pull carts and plow the soil. Donkeys, horses, and eventually camels were also harnessed in the same region to convey people and goods.

The agricultural transformation, also called the Neolithic Revolution, was very probably the most momentous turn in the progress of humankind, and many believe it to be the real beginning of civilization. It first took place in the Near East approximately 10 millennia ago, initially in the

relatively humid subregions where precipitation was sufficiently abundant and regular to permit rain-fed farming. Agriculture was later extended to river valleys in the drier zones by means of irrigation, which was based on the diversion of water from rivers onto adjacent flat lands. At the same time, humans discovered that, by kneading and shaping lumps of clayey soil and then baking them in ovens, they could fashion vessels for storing water as well as for cooking food. Bricks made of molded clay served for the construction of homes and grain storages, while tablets of clay could be imprinted with various signs to form permanent records in an early form of writing called cuneiform. Later still, people learned to extract, alloy, and mold metals such as copper and iron and to fashion them into implements.

Rain-fed and/or irrigated farming practices, along with ceramics and metallurgy, later spread to, or were developed independently in, most of the other human-inhabited regions around the world.

The ability to raise crops and livestock, while resulting in a larger and more secure supply of food than was possible previously, definitely required attachment to controllable sections of land and hence brought about the growth of permanent settlements and of larger coordinated communities. The economic and physical security so gained accelerated the process of population growth and necessitated further expansion and intensification of production.

LAND DEGRADATION

The evolution of agriculture left a strong imprint on the land in many regions. The vegetation, animal populations, slopes, valleys, and soil cover of land units were radically altered. The practices of tillage and fallowing, terracing, and irrigation and drainage, as well as grazing of flocks, further accelerated soil erosion in sloping lands and sedimentation in lowlands. Soil lost from denuded cultivated slopes could not be regenerated unless the land was allowed to revert to its vegetative cover for many decades or centuries. Moreover, soils that were irrigated in poorly drained river valleys tended to become waterlogged and saline, with the result that the practice of farming could not be sustained there in the long run.

The same anthropogenic processes, which began in the early history of civilization, have continued ever since on a more extensive scale. Especially vulnerable are cultivated and overgrazed soils in semiarid regions, where droughts occur periodically, accompanied by strong winds that deflate the bare and pulverized soil surface, and where the intermittent onset of rains causes further damage. Consequently, once-productive lands may become so degraded as to acquire desert-like characteristics. Hence, the process of land degradation in semiarid regions has been termed “desertification.”

Examples of large-scale land degradation can be cited in many parts of the world. A case in point is the famous

“Dust Bowl” that took place in the Southern Great Plains of the United States in the 1930s and that caused the uprooting and migration of entire farming communities. A similar process has been occurring on a vaster scale in the African Sahel which is the continent-wide semiarid savanna belt that lies between the Sahara desert in the north and the tropical forests in the south. A particularly disastrous example of waterlogging and salination because of irrigation is seen in the Aral Sea Basin of Central Asia (Uzbekistan, Turkmenistan, and Kazakhstan). The same processes are occurring in highly developed parts of the world, such as the Murray–Darling Basin of Australia or San Joaquin Valley of California. Even more consequential is the large-scale destruction of rainforests and the loss of biodiversity resulting from the expansion of agriculture in the tropical zones of South America, Central Africa, and Southeast Asia, where the warm temperatures and high humidity contribute to the rapid decomposition of the soil’s original organic matter content and to the deterioration of the soil’s structure as well as its nutrient content.

THE IMPERATIVE TO IMPROVE SOIL MANAGEMENT

In addition to its uses for agricultural production, the soil also serves human communities as a depository of waste products—domestic, agricultural, and industrial. In principle, the soil is endowed with inherent capacities to absorb, retain, and decompose many waste materials and pathogenic agents that might otherwise accumulate to poison the environment. However, those capacities are limited, and when exceeded by the application of larger than normal quantities of potentially toxic wastes (such as pesticides, heavy metals, hydrocarbons, and non-biodegradable synthetic compounds), the soil may merely be a way station, detaining but not retaining harmful agents, which it eventually releases to the biosphere.

Prospects for improving the management of soils in the future will likely be affected by the threat of global warming because of the increasing concentrations of radiatively active gases in the atmosphere. In a warmer world, all weather phenomena may be intensified, with more frequent and stronger rainstorms punctuating longer and more severe droughts. Such a trend will require far reaching and expensive adjustments in the zonation and methodology of agricultural production as well as in water storage and supply facilities.

CONCLUSION

Humanity depends on the soil more crucially than ever, not only because population has grown but also because available soil and water resources have diminished and deteriorated. Our needs and those of future generations require us to seek better ways to manage those precious resources

judiciously and sustainably. What past generations despoiled inadvertently owing to lack of comprehensive scientific knowledge or social-environmental consciousness, we must begin to rectify deliberately. Developing, disseminating, and applying knowledge of the soil and its processes are essential tasks if we are to ensure the lasting welfare of humanity as well as the terrestrial ecosystem as a whole.

Human Dimensions: Soil Sustainability

Mary Seely

Patrik Klintenberg

Claus Hager

Desert Research Foundation of Namibia, Windhoek, Namibia

Abstract

Human dimensions of soil sustainability are manifold. Soil sustainability depends on a variety of human actions that influence the soil inadvertently or with deliberate intention to do so. Inadvertent influences may be brought about by a diversity of socioeconomic changes including, inter alia, the global, national, or local economy; political regimes; changing global markets; urban expansion; labor availability; farming systems; residential patterns; or local development. These changes may be beyond the control of the individual farmer, cooperative, or industry or be based on the farmers' selection of alternative socioeconomic priorities unrelated to soil productivity. Most deliberate influences on the soil focus on enhancing its productivity or its long-term stewardship, particularly in developed economies. This entry provides examples from a developing country of human dimensions indirectly or directly related to soil sustainability.

INTRODUCTION

The goal of this entry is to use the example of central northern Namibia to probe some of the human dimensions indirectly or directly related to soil sustainability. Although the examples are specific, the principles elaborated are broadly applicable. Central northern Namibia is the most densely populated area of the country, where a dual farming system of crop production, primarily pearl millet, and livestock management is pursued under low rainfall on Kalahari sands in an ephemeral wetland.^[1] The population has grown eightfold in the 20th century during which time human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) appeared and an imperfect market economy became established, all leading to major socioeconomic changes.

People and their livestock settled in the Cuvelai inland delta approximately 400 years ago.^[1] Settlement began by clearing and cultivating the stabilized Kalahari dunes lying among ephemeral watercourses (oshanas) and shallow lakes. Early farms were laid out perpendicular to the oshanas sometimes encompassing as many as 8 or 10 of the 26 different recognized indigenous land units.^[2] Rainfall is the primary factor determining the time of planting, and in poor rainfall years, planting is commonly staggered to ensure at least some harvest. In a well-established farm, the most fertile soil types are chosen for early planting. Originally, the low population allowed a system of livestock management that brought cattle close to the crop farms for part of the year where they were enclosed and manure could accumulate. They were allowed into the fields after the millet

harvest to graze on crop residues and deposit manure directly. With an increasing population and smaller, more closely situated farms, livestock remain at cattle posts throughout the year, while millet stalks are used, inter alia, for household construction and fencing.^[3] In 2005, crop productivity of this area is extremely low at 250 kg/ha,^[4] less than a third of the global average yield.^[5]

SOCIOECONOMIC DETERMINANTS OF SOIL SUSTAINABILITY

Changes in labor availability have a major impact on farming practices and consequently on use, fertility, and sustainability of soil. In the past, men were responsible for the preparation of the fields for planting, which included distributing manure from the livestock enclosures.^[3] In the past, development of migrant labor meant that most men worked away from home. In some instances, remittances were available and used to support additional family members in the homestead providing alternative labor. The cash economy, fuelled by globalization, and preference for white-collar work, particularly with government, draw the men and some women to distant towns for jobs and young men to the capital in search of employment. Many of the men remaining at the homestead are old-age pensioners. As a consequence, smaller fields may be cultivated, often by older women, while the absence of livestock in the vicinity means little or no application of manure. Confounding this situation is the requirement for children to be in school, often in boarding schools far from the homestead, so this

source of part-time labor is also unavailable. In 2003, the impact on farming labor and soil management is the advent of HIV and AIDS.^[6] This has reduced the life expectancy of people in the rural areas by approximately 20 years and has impacted primarily on the productive population directly removing people from the labor pool, necessitating time and effort for care of those affected and reducing remittances. For wealthier farmers, hiring labor to fill the gap is an option but one that is only used for livestock herders, not for addressing crop farming or the soil quality that makes this profitable.

Changing approaches to farm and homestead management have also had an impact on soil management and sustainability. With the increase in population, shifting cultivation and leaving fields to fallow is no longer an option. New fields are opened up, but these are on deeper sandy soils or soils with shallow hardpans away from the central ephemeral wetlands. At the same time, transport of manure from cattle posts, often at distant grazing areas, is too expensive for most. Alternative fertilizer sources are also considered too expensive and are hardly used, while available cash is spent on livestock for its cultural and status values.^[1]

Another development affecting soils is the construction of permanent brick houses. Previously households were constructed of wood with thatched roofs, which were moved short distances at approximately decadal intervals. Deforestation and lack of suitable building materials, combined with the desire for a modern home, have promoted this shift. The site of the previous household was considered more fertile than the surrounding soil and usually planted for the first rains.^[2] The shade trees, which had been protected at the previous homestead, continued to provide shade and reduced drying of the soil.^[7]

Mainly, the presence of women at the homestead to prepare the fields and manage the crop has led to greater dependency on tractors or draught animals. This broad-scale approach has reduced the ability to selectively plant on particular soil types, often only several square meters in size. Interest in and knowledge of different soil characteristics are decreasing. The introduction of government-subsidized chemical fertilizers has also contributed to this shift. Moreover, the change from polygamy to monogamy in household composition has reduced the availability of womanpower to prepare fields by hand in the absence of men to do this traditional job.

MANAGEMENT OF SOIL QUALITY AND VARIABILITY

Direct management of soil character and its variability to increase productivity is practiced according to the options available. Farmer selection of farms to span several soil types, elevations, and distances, ranging from low dune crests to oshanas, was an approach used before the increased population had occupied all available,

high-quality land.^[8] Livestock were managed to provide manure directly to the crop fields when low human population pressure allowed livestock to move between the grazing area and the homestead with its crop fields.

When the population density was low and before the advent of tractors, trees were grown within fields providing shade and contributing to soil moisture retention. This tradition may not have represented direct management of soil moisture, but the value of maintaining selected trees within the crop fields is recognized.^[9]

Knowledge of soil types is used extensively by older farmers,^[8] although maintenance of this information base is questioned by researchers.^[9] Further studies have indicated that the main local indicators of soil types are reduced to crop yield and soil color with more detailed knowledge restricted to older persons. Awareness of the presence of a hard pan, which influences the selection of crops, e.g. millet vs. sorghum, remains.

Application of manure and crop residues through management of livestock was a primary tool to manage soil fertility. However, manual application of crop residues and ashes from crop residues, as well as application of household waste, is being used.^[9] In general, the cropping system on Kalahari sands in the oshana area is considered to be one of the low-input and low-output systems providing some basic sustenance. Nevertheless, it receives little focused attention in a culture entirely based on livestock for its social and status value.

Recommendations for soil and productivity improvement have included using legumes interplanted among millet and other cereal crops. Traditionally, some legumes were planted with millet, and this type of soil improvement continues.^[3]

The concept of conservation tillage has been introduced and is being used in a few pilot sites. Conservation tillage concentrates on the use of scarce resources (labor, seeds, fertilizer and organic matter, and water) on selected areas, chosen on the basis of indigenous knowledge of soil types and microtopography. Furrows are intensively prepared throughout the year and repeatedly over the seasons, with the advantage of spreading labor requirements and building up soil structure and water retention capacity in the plant root zone.^[10]

CONCLUSION

The human dimensions of soil sustainability are varied. Most are inadvertent relationships brought about by socioeconomic developments at local, national, or global scale. These developments include family structure, age, migration, labor availability, gender, health, farm management, and residential and urban expansion as well as the changing environmental conditions and strong cattle culture. Some relationships are based on direct interventions by people living on the soil or by external sources such as government directives or global markets. In the developed countries,

economic aspects drive the relationship between soil productivity and sustainability. In the developing countries, rapidly changing social and local to national economic conditions tend to be most important.

Human Health and Soil

Charles F. Sing

David B. Sing

Department of Human Genetics, University of Michigan, Ann Arbor, Michigan, U.S.A.

Abstract

Soil is a complex system of minerals, organic matter, and biota that covers the terrestrial earth in a layer above the underlying bedrock. Soil is the ecological support structure for all terrestrial life, including humans. Human health is an optimal state of general physiological and psychological well-being associated with a lack of disease.

Health is a dynamic emergent property that unfolds over the lifetime of the individual as a consequence of the complex interactions of an inherited biological predisposition with exposures to environmental agents. The relationship of soil with human health is a subset of an ecological whole, which includes the entire ecosystem of the planet. Agriculture is a human activity designed to produce domesticated plants and animals and involves the modification of landscapes and soils and the breeding of plants and animals to maximize the production of commodities to be processed into food. Modern agriculture is organized into farms. Farms are human-operated land management systems in which farming activities replace normal ecosystem feedback controls. The relationships between soil, food, and human health are first derivatives of local and national agricultural practices and policies that are influenced by the economic and cultural norms of society. The management of agricultural soil is a proven force in the relationship of soil and human well-being. While the ecology of soils is poorly understood, research in the fields of epigenetics and nutrigenomics suggests a deeply embedded crucial relationship between human health and our genetic potential for responding to exposures to nutrients in food and to contact with the soil. Epigenetics is the study of the influences of environmental exposures on the expression and imprinting of genes. The field of nutrigenomics studies the role of nutrients on gene expression. The study of the role of exposures to soil constituents and components of food in determining gene function is an exciting field of research, which provides the possibility to understand the biological mechanisms that are responsible for the observed associations between soil biology and human phenotypes of health and disease.

INTRODUCTION

Soil is the ecological support structure for all terrestrial life, including humans. As the advent of agriculture, our species has developed a strong relationship with soils, as our nutrient and energy requirements are met by the cultivation and processing of plants and animals grown in and on the soil. Civilizations have risen and fallen on the quality and management of their agricultural soils. Biological connections have been discovered between human health and the nutritive elements and biota found indigenously in soils. There is a great potential for discovery, both in the ecology and biology of soils and in their relationships with human health. Although the ecology of soils is poorly understood, research in the fields of epigenetics and nutrigenomics suggests a deeply embedded crucial relationship between human health and our genetic potential for responding to exposures to nutrients in food and to contact with the soil. In this entry, we introduce the fundamental relationships between soil and human health and call attention to the potential for understanding those relationships that are emerging as a consequence of advances in genetic biology.

Soil is a complex system of air, water, minerals, organic matter, and biota that covers the terrestrial earth in a layer above the underlying bedrock. The multitude of interactions among the myriad constituents of soil has been interpreted to infer that soil is a highly dynamic, ecologically complex, and diverse living entity (see the entry *Human Society and Soil*, p. 1123). A healthy agricultural soil is characterized by a diverse compilation of soil components, including a mixture of biota and organic materials,^[1] that provide the condition of optimal fertility for growing healthy plants for animal feed and for processing into human food. Food is consumable material derived from plants and animals that have been selected by humans for their nutritive and energy values and for their ease of domestication, commodification, and processing. Human health is an optimal state of general physiological and psychological well-being associated with a lack of disease. Health is a dynamic emergent property that unfolds over the lifetime of the individual as a consequence of the complex interactions of an inherited biological predisposition with exposures to environmental agents, which include direct contact with soil and dietary components that are

derived from the soil through plants and animals.^[2] Agriculture is a human activity designed to produce domesticated plants and animals. Modern agriculture involves the modification of landscapes and soils and the breeding of plants and animals to optimize the production of commodities to be processed into food. Modern agriculture is organized into farms. Farms are human-operated land management systems in which farming activities replace normal ecosystem feedback controls.^[3] Taken as a whole, the relationship of soil with human health is a subset of an ecological whole, which includes the entire ecosystem of the planet. This relationship is influenced by the cultural practices of the people who grow and eat the food.

Despite an age-old consensual cultural agreement that there is a connection between the health of the soil and human health, convincing evidence for direct connections is scant. Our limited understanding of the efficacy of soil in regard to human health has been mainly concerned with food and food products. As a nascent understanding of soil ecology becomes more developed, it is becoming apparent that human health is also influenced by a direct contact with the soil biota and with the organic and inorganic components of the soil.^[4,5] For approximately 10,000 years since the beginning of agriculture, human culture has heavily influenced the management of soils and how plants and animals are selected, grown, and processed into food. Later, we briefly review the direct effects of soil on human health, the effects of soil on health translated through food, and the effects of cultural practices that impact the soil health–human health relationship.

SOIL CONTACT AND HUMAN HEALTH

Throughout our evolutionary past, human health has been influenced by a contact with the soil, either directly by dietary ingestion of soil (geophagy) or indirectly by breathing airborne soil constituents or by ingesting soil constituents in drinking water. Soil contact can expose humans to soil elements and biota that are beneficial to health and to toxic materials and pathogenic organisms that contribute to the risk of disease. Geophagy developed in preagricultural humans as a method of ingesting nutritive elements otherwise not found in available foods and as a way to detoxify certain plant products to make them edible.^[6] Ingestion of certain clays has been an important human dietary behavior since the origin of our species, providing nutritionally significant amounts of nutritive elements in regions where diets are otherwise lacking in these constituents. It has been suggested by Johns and others that the earliest cultivation of certain poisonous plants, such as potato, depended on human geophagic knowledge of the detoxifying properties of certain soils.

Geophagy persists as a developmental behavior of young children who consume soil and other non-food materials as a means of exploring and assessing their

environment.^[7] In urban and suburban settings, such geophagic activity can expose individuals to toxins that have accumulated in the soil, such as lead and other heavy metals, and pathogenic organisms, such as clostridium tetani (causing tetanus) and helminth nematodes (hookworm, etc.).^[7–9] Conversely, there are also soil biota that may be ingested that are beneficial to the development of the human immune system. It has been suggested that the urbanization of human populations and a cultural preference for an antiseptic microenvironment have, for many people, created a physical disconnect with soils that may be responsible for a marked increase in asthma and other atopic diseases in Western cultures.^[10]

From an epidemiological perspective, the discussion of the relationship between contact with the soil and human health has focused on specific environmental exposures that lead to disease or nutritional toxicity.^[4,5] Potential adverse exposures include artificially introduced toxic materials, e.g., contained in fertilizers and pesticides, biologic pathogens, and certain naturally occurring elements in toxic concentrations. Unhealthy levels of some elements may accumulate in livestock, fruits, and vegetables. Conversely, consuming foods grown in soils with low levels of certain essential elements can lead to nutritive deficiencies in humans. Damage to produce during production can allow for toxins and pathogens existing in the soil to enter and accumulate in the damaged fruits and vegetables. Humans are then exposed to these toxins and pathogens when they consume damaged or improperly cleansed fruits and vegetables.^[4,5,6]

Leaching of soil nutrients, such as nitrates, from agricultural soils into groundwater is a common process that connects soil with human health. Nitrogen is an essential component in the growth and metabolism of all living systems and exists environmentally in a number of nitrogenous compounds, including ammonia (NH₄), nitrates (NO₃), and nitrites (NO₂). As the advent of nitrogen-rich fertilizers in the early 20th century, food production has greatly increased, as has the amount of nitrates introduced into agricultural soils. These excess nitrates accumulate in the soil and are leached into groundwater. Nitrate-consuming bacteria in the soil and groundwater can convert the excess nitrates into nitrites, which are toxic and have serious implications for human health. Intrauterine exposure to high levels of maternal dietary nitrites in the drinking water can lead to methemoglobinemia (blue-baby syndrome), a potentially fatal disease.^[11] People living in agricultural areas where high-nitrogen fertilizers are applied to the soil and whose source of drinking water is groundwater wells are at the greatest risk of exposure to toxic levels of nitrites.

HEALTHY SOIL, HEALTHY FOOD, AND HUMAN HEALTH

The connection between soil health and human health through foods is largely unappreciated where food is

abundant and the quantity of fertile soils is not a limiting factor. Most foods consist of processed plant and animal products that provide energy and nutrients for developing and maintaining the body. The dominant American food culture is characterized by food products that are produced in high quantity and are highly processed amalgams of different commodities from various, and often geographically disparate, locations. Processed foods high in refined carbohydrates (sugar) and certain types of fat have been shown to be detrimental to human health.^[12,13] In North America over the past several decades, a marked increase in diet-related human illnesses and chronic morbid conditions, including obesity, cardiovascular diseases, diabetes, and certain cancers of the digestive and endocrine systems, have been associated with increased availability of fatty and sugary food products.^[12,13] In general, North American agriculture supports a food industry that produces inexpensive, convenient, high-calorie, nutrient-poor food products that can be mass processed and distributed to a public that expects their foods to be inexpensive, convenient, rich in flavor, and high in caloric potential and that perceives more nutritive, less-processed foods as expensive, and more time-consuming to prepare and consume. An emerging awareness of the health consequences of this food culture is reflected in a surge of consumer interest in organic and locally grown foods in North America and Europe.^[14,15]

In North America, the soil where most food is grown is of relatively high quality, assuring any number of nutritious food choices to be produced at high levels. In regions of the world where agricultural soils are marginal or degraded, overall crop production is often inadequate, and the nutritive quality of the foods available is limited by the poor quality of the soils that remain arable. Consequently, the people of these regions often suffer from malnutrition and famine and have higher rates of disease and shorter life spans.

There is abundant evidence of the deleterious nutritional effects of eating foods grown in soils that have low levels of certain naturally occurring trace elements.^[4,5,16,17] Low levels of dietary iodine can lead to an array of iodine deficiency disorders, including goiter, hyperthyroidism, and childhood physical and mental retardation. Soils that are low in iodine are found throughout the world. In response to the nearly global effects of iodine deficiency disorders, various international groups, including United Nations Children's Fund and World Health Organization, created the International Council of Control of Iodine Deficiency Disorders (ICCIDD) in 1985, with the goal of eradicating iodine deficiency. The most effective result of ICCIDD has been the effort toward the universal iodization of salt. Iodized salt is available in most of the world, and as a result, iodine deficiency disorders have dropped dramatically.^[16] Selenium is another globally distributed soil trace element that has been found to be essential to human metabolism and health. Selenium deficiency has been linked to a number of diseases and disorders, including viral infections, immune system disorders, cancer, cardiovascular diseases, low sperm motility,

higher rates of miscarriage, and mood disorders, such as depression. Dietary selenium is crucially involved with selenocysteine, the 21st amino acid, which promotes the production of selenoproteins. Most of the selenoproteins that have been identified are involved in a number of important metabolic functions, revealing a direct relationship between the levels of dietary selenium and human health.^[17] Other such relationships between soil trace elements, the nutritional composition of food processed from plants grown on that soil, and human health have been well documented.^[4]

It has been suggested that organically grown food may be beneficial to human health.^[18–20] Public interest in organic agriculture, whereby foods are produced without the use of synthetic pesticides and herbicides, soluble fertilizers, non-therapeutic antibiotics, and growth hormones, has popularized the concept of healthy food derived from healthy soil. Organic foods are often selected by consumers for their lack of these agricultural inputs and for the subsequent reduction in the negative impacts of farming on the ecology of soil and water. However, there is a lack of credible research to support anecdotal claims that organic methods produce foods nutritionally “healthier” than foods grown using conventional agricultural practices. Further work describing nutritional benefits of organic vs. conventionally produced food has been criticized for the general lack of definitive data.^[3,21,22] Regardless of this, the further rise in public interest in organic foods reflects an increased cultural concern for a healthier lifestyle that is associated with healthier foods. Although more organic products are available in the marketplace, they remain relatively rare, specialized, and expensive when compared with the majority of food products, which are produced and processed conventionally.^[3]

Epigenetics is the study of the impact of exposures to environmental agents on the expression of genes and how this relationship influences the development and, in particular, the emergence of measures of health and disease with aging.^[23] The field of nutrigenomics studies the impact of nutrients on gene expression.^[24] Research involving the role of folic acid in the diet suggests an epigenetic relationship between nutrition of the mother and the functions of the offspring's genetic make up during development, which can manifest phenotypically later in life.^[25] The direct exposures to soil constituents and components of food in determining gene function are an exciting field of research, which provide the possibility for a better understanding of the biological mechanisms that are responsible for the observed associations between soil biology and human phenotypes of health and disease.

THE IMPACT OF CULTURAL PRACTICES ON SOIL, HUMAN HEALTH, AND THE SURVIVAL OF CIVILIZATIONS

The relationships between soil, food, and human health are the first derivatives of local and national agricultural

practices and policies that are influenced by the economic and cultural norms of society.^[26,27] The management of agricultural soil is a proven force in the relationship between soil and human well-being. Modern agriculture policies and market infrastructures encourage large monocultures of crops such as corn and soybeans, which are grown as inputs for processed foods and biofuel production. When farmed using conventional methods, monocultures can contribute to loss of soil through erosion and degradation of soil health, which can have a major impact of the sustainability of agriculture, with subsequent effects on the nutritional health of the societies involved.

High-tech monoculture farming operations in North America and Asia have contributed to increased rates of soil degradation. Lal suggests that cultures that develop a spiritual relationship with the soil, whereby the soil is understood to be a living entity worthy of respect, encourage agricultural methods that functionally resist the degrading effects of technology on the soil. By integrating social and spiritual beliefs about soil into agricultural practice, such cultures are more likely to persist.^[5,28] The benefits of traditional agricultural methods, such as crop rotation, low- and no-tillage methods, composting of organic materials, the use of green and brown manures, and the use of other traditional methods that foster a sustainable agriculture, are well documented.^[15,20] When compared with the conventional methods alone, these traditional agricultural methods decrease tillage and fuel, fertilizer, and pesticide inputs and have been shown to keep production levels high, decrease soil loss, and improve soil health.^[7,15,20]

A further increase in public discussion of the environmental and health benefits of organically produced foods has increased cultural concern for the potential non-sustainability of conventional farming methods that degrade soil. Modern organic methods of production and processing follow ethical guidelines that include sustainable soil management, reduced fertilizer, herbicide and pesticide inputs, and an acknowledgment of complex interrelationships between the soil, the food commodities being produced, the humans that produce and consume the food, and the environment.^[15] In the United States, the number of U.S. Department of Agriculture–certified organic acres of agricultural land has increased from just less than 1 million acres in 1992 to more than 4 million acres in 2005. This represents less than 1% of the total acreage dedicated to agriculture in the United States.^[29,30] Newer agricultural practices that blend aspects of both conventional and traditional methods have been shown to keep production levels high while decreasing fuel, fertilizer, herbicide, and pesticide inputs and decreasing soil degradation (when compared with conventional methods alone).^[3,15,20] Kirschenmann summarizes such a new sustainable food system “that meets the challenges of our post-industrial era ... that is more resilient, more secure, more energy efficient, and provides us with healthier food and more pleasurable eating than the industrial food system

currently offers us.”^[31] Hopefully, the increased public awareness of sustainable and organic methods of food production and the integration of sustainable and conventional practices has started a trend toward better soil management.

THE FUTURE

Regardless of our knowledge of food production and awareness of the relationship between food and health, there is a void of academic work directly connecting the ecology and biology of the soil with human health. The role of soil ecology in determining human health is the least understood component of the agricultural process. Our methods for understanding soil ecology give only an incomplete picture of the soil-microbe community.^[32,33] In particular, the relationship between soil-microbe ecosystems and the observed health benefits of organically grown food has to be fully appreciated and is emerging from research in progress.^[21,22,26,34–36] Insights offered by research on the epigenetic effects of direct and indirect exposures to soil constituents and constituents of food hold promise for establishing the role of the human genome in connecting soil with human health.

CONCLUSION

Finally, it is relevant to call attention to that the historic decline of past civilizations has been linked directly to their failure to properly manage their agricultural soils. The past 10 millennia have seen the rise and fall of many human civilizations, and one recurring theme through most of the failures has been the depletion of the agricultural soils due to poor soil management.^[28,37] The parasitic, forceful, and unsustainable occupation of soils by humans and human activities reveals modern humans as a pathogenic agent, negatively “afflicting” the soil with unsustainable agricultural methods until both the host (soil) and parasite (humans) are exhausted. The future well-being of our species depends, in no small part, on how we manage the production of food while remaining mindful of the relationship between soil and human health.

Human Society and Soil

Rattan Lal

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Soil for modern societies is even more important than ever before. The increase in importance lies in the fact that soil resources of the world are: 1) finite; 2) non-renewable over the human time frame; 3) liable to misuse and mismanagement; 4) unevenly distributed among biomes and ecoregions and 5) highly variable over time and space. Area under prime soils, with few or no limitations to intensive use for agricultural production, is rapidly shrinking because of soil degradation, conversion to non-agricultural uses, and urbanization. This entry describes the dependence of human society on soil in both ancient and modern eras, and the need for maintaining and enhancing soil quality for achieving food security and improving environment quality.

INTRODUCTION

Humans are the most highly evolved animals who, in addition to flesh and skeleton, have intellectual capacity to perceive, rationalize, and develop technological innovations to overcome nature's constraints to meet their needs. There is a strong interdependence between soil and humans. Soil is the 3-D layer of earth's crust that, through numerous biophysical and chemical interactive processes, is capable of supporting plant and animal life and moderating environment (air and water) quality. Rather than a mere combination of inorganic and organic substances to varying proportions represented among different soil types, soil is a living entity. It is full of life, highly dynamic, and ceases to produce biomass and purify water and air when life in it ceases to exist due to natural or human-induced causes. Thus, there exists a strong interrelationship between soil and humans. Ever since the evolution of humans on earth, the quality of life and number of humans in any ecoregion or biome have depended on the quality and resilience characteristics of the soils of that region. While human societies rose and vanished, along with the quality of soil that supported them, they also changed soil quality in a manner that no other species of the animal kingdom has ever done throughout earth's history. The fate of humans and the soil that supports its society is so closely intertwined that it is difficult to understand the nature of one without knowing the properties and dynamics of the other. Humans have manipulated soils to meet the nutritional needs of their body and the spiritual needs of their soul. In that process, they have left an indelible mark on soil quality. As Lowdermilk^[1] wrote, "Individual nations and civilizations write their records on the land—a record that is easy to read by those who

understand the simple language of the land." The extent and severity of change in soil quality due to human-induced perturbation depend on the demands based on human needs and expectations.

Soil is the most basic of all natural resources, because most processes governing terrestrial life depend on it. Important among these processes are: 1) biomass productivity, 2) purification of water, 3) detoxification of pollutants, 4) recycling of elements, and 5) resilience and restoration of ecosystems. Hugh Hammond Bennett, father of the soil conservation movement in the United States, wrote "Out of the long list of nature's gifts to man, none is perhaps so utterly essential to human life as soil." The human history is intimately linked to soil and its quality. That is why "soil" or "Mother Earth" has been held sacred and worshipped by many ancient cultures. Ancient Hindus and Buddhists worshipped earth as Dharra, Vasundharra, Buhumi, and Prithvi as sacred. The word Dharra has the same roots as the Latin word Terra. The ancient Greeks worshipped the earth as Gaea or the Mother Earth. Water, another important constituent of the land and essential for life, is also held sacred in many cultures. The Koran, sacred to the followers of Islam, states that "with water we have made all living things." Similar beliefs exist in Hebrew, Christian, and other cultures.^[2]

SOIL AND ANCIENT SOCIETIES

The history of human civilization is based on the relation between humans and soil, humans' influence on soil quality, and humans' perception of how to manage soil resources. Hyams^[3] outlined three types of interactions

between soil and ancient societies, depending on the renewability of the soil and the managerial skills of the evolving human society.

Soil Parasitism

Parasitism implies the life of an organism through exploitation (and in extreme cases, eventual debilitation) of its host. Humans exist as parasites on soils because of the dawn of civilization and evolution of structured society. Some alluvial soils, due to their natural rejuvenation and renewability, have supported human societies for millennia. Examples of such constantly renewed alluvial soils include those in the valleys of the Nile, the Euphrates–Tigris, the Indus, the Yangtze, and the Hwang-Ho. Similar to alluvium, some loess (wind-borne) soils also have the renewability and capacity to withstand human exploitation for a long time. In arid and semiarid regions where loess is formed, soils must have adequate supply of good quality water to support and sustain human society for an extended period of time. Because of their natural renewability, caused by annual floods, societies living off the alluvial soils did not have to discover ameliorative tools (e.g., plow, manure, and other amendments).

Soil Occupation or Militaries

In contrast to the deltaic soils of the Nile, those of the Euphrates–Tigris river system were easily eroded and degraded because of undulating terrain. For example, the soils of ancient Babylon were desolated by misuse and abuse over an extended period of time. Sustaining production on these soils implied input of energy, nutrients, and water. Therefore, it was in this region where innovations such as the plow, irrigation, and manuring were introduced to alleviate soil-related constraints to crop production. The “ard” or plow evolved from a planting stick about 10,000–12,000 years ago,^[4] probably in the Middle East.^[5] Yet irrigation and soil erosion cannot be taken for granted. After all, it was the neglect of ancient canals, which created waterlogging and salinity on the one hand, and erosion in the catchment, which led to siltation of waterways and reservoirs on the other. Agriculture that was thriving about 10,000 B.C. in Mesopotamia, present-day Iraq, was converted to desert and shifting sand dunes by deforestation and erosion of the surrounding hills.^[1,6] There is a lot of similarity in ecosystems of Euphrates–Tigris and Indus valleys. Salinity, erosion (by water and wind), and siltation also played havoc with human-occupied soils of the Indus. Widespread deforestation for wood for brick-making in the Indus Valley^[3] might have caused severe problems of erosion and degradation. The collapse of the 1700-year old Mayan civilization in Guatemala around 900 A.D. is also attributed to accelerated soil erosion.^[7] Increase in population caused soil depletion, and the Mayan culture paid the ultimate price.^[8] Military

occupation of any form, on a soil or society, cannot survive/sustain for an extended period.

Humans as Soil Pathogens

There are many examples where humans have been the “afflicting” and the soil, the “afflicted” species in functions rather than in form. A disease is caused by imbalance between the activities of afflicting (parasite) over that of the afflicted (host) species, leading to eventual collapse of both host and parasite. The extinction of many ancient societies (e.g., Mesopotamia in Iraq, ancient kingdoms of Sardis and Lydia in Turkey, the Mayan kingdom in Guatemala, etc.) are but a few examples of the severe cases of humans afflicting soil, leading to an eventual collapse of both. In contrast to the vanquished, ancient societies that realized that soil is to be respected and worshipped as a living entity have thrived and flourished.

THE VANISHING SOIL AND MODERN SOCIETY

The per capita arable land area is rapidly decreasing due to an ever-increasing human population. In 1995, the per capita land area was 0.23 ha worldwide, 0.23 ha in Africa, 0.20 ha in Latin America, 0.89 ha in North America, 0.12 ha in Asia, 0.17 ha in Europe, and 1.8 ha in Oceania. By 2050, even if there is no soil degradation and conversion to non-agricultural uses, the per capita land area will change to 0.14 ha worldwide, 0.08 ha in Africa, 0.11 ha in Latin America, 0.69 ha in North America, 0.07 ha in Asia, 0.19 ha in Europe, and 1.1 ha in Oceania. Similar to the arable land area, world grain harvested area per person declined from 0.23 ha in 1950 to 0.11 ha in 1998^[9] and will decrease to 0.07 ha by 2050.^[10] These vanishing soil resources imply that the basic necessities of life (e.g., food, feed, fuel, and fiber) will have to be met from low per capita land area and likely with adverse moisture/rainfall and temperature regimes due to the projected greenhouse effect. The cereal production of 2081 million Mg in 1998 will have to be increased by 62% in 2025 and 121% in 2050 to meet the food demands.^[11] The percentage increase in cereal production will be much greater in the developing countries of Asia and Africa.^[11]

The importance of soil resources on global food security cannot be overemphasized. Despite impressive gains in food production brought about by the Green Revolution technology, the problem of food insecurity persists in several less-endowed and densely populated regions of the world. The food insecure population of the world was 960, 938, 831, and 791 millions in 1970, 1980, 1990, and 1996, respectively, and is projected to be 680 million in 2010.^[12,13] There is also a widespread problem of malnutrition,^[14] which is accentuated by food grown on nutrient-deficient and degraded soils.

The threat of pending famine was voiced by Thomas Malthus in 1798 when the world population was merely 940 million. Since then, the world population has multiplied geometrically, as Malthus predicted, to 1.26, 1.65, 2.52, and 6.06 billions in 1850, 1900, 1950, and 2000, respectively.^[15–17] In 1000 years, from year 1000 to 2000, the human race has multiplied 20-fold and is increasing at the rate of 73 million or 1.3%/yr. The population is projected to be 7.5 billion by 2020 and 9.4 billion by 2050. The welfare of the population depends on soil quality and resilience under an intensive agricultural use. Several global challenges facing human society at the onset of the 21st century (Table 1) will have to be met through sustainable use of the world's soil resources.

SOIL–HUMAN SYMBIOSIS

The incidence of undernourishment in developing countries will persist during the first half of the 21st century. The number of undernourished people in developing countries will be 610 million by 2015 and 443 million by 2030.^[18] The challenge lies in improving the quality of life while diminishing the ecological foot prints of natural resources. Thus, soil resources must be managed, improved, and restored, if the challenges of the 21st century (Table 1) are to be successfully met. The large human population (6 billion and 9.4 billion by 2050) cannot survive by parasitism, militaries, or pathogenic strategies. Humans have to live in harmony or symbiosis with soil. Humans, through their inquisitive nature and innovative instincts, have the capacity to meet the challenges of the growing population.

Table 1 Challenges posed by human society at the threshold of the 21st century that world soils must meet.

Challenge	Status	Rate of change
World population	6 billion	+1.3%/yr
Food insecure population	790 million	–1.0%/yr
Soil degradation	1966 Mha	+5–10 Mha/yr
Desertification	1016 Mha	+5.8 Mha/yr
Global irrigated area per person	0.045 ha	–1.3%/yr
World grain harvested area per person	0.11 ha	–0.55%/yr
Forested area per capita	0.59 ha	–0.78%/yr
Atmospheric concentration of GHGs		
1) CO ₂	370 ppmv	+0.5%/yr
2) CH ₄	1.74 ppmv	+0.75%/yr
3) N ₂ O	311 ppbv	+0.25%/yr

Source: From Lal^[9] and Brown, Gardner, et al.^[16]

As Stevenson wrote, “Nature is neutral. Man has wrested from nature the power to make the world a desert or to make the desert bloom.” The power to make the desert bloom lies in the realization of maintaining and enhancing soil quality. The concept of soil quality in one form or another has been used by agricultural philosophers and writers for some 2500 years. An agriculturist of Moorish Spain, *Ibn-Al-Awam* wrote several volumes during the 12th century on agricultural issues. The book *Kitab al-Felhah* or *Book of Agriculture* was translated into Spanish in 1802 and was brought to public attention in the *Encyclopedia of Islam* (1760–1777). In this book, the author writes, “The first step in the science of the agriculture is the recognition of soils and of how to distinguish that which is of good quality and that which is of inferior quality” (vol. 1, p. 23).^[1] The concept of soil quality, well developed and understood for its management and enhancement, has to be used in a “symbiotic” manner for meeting the challenge of the modern era. These challenges have to be met through: 1) restoration of degraded soils, 2) enhancement of soil organic matter content and soil quality, 3) intensification of agriculture on prime soils, 4) minimizing risks of erosion and soil degradation by other processes, and 5) enhancing efficiency of all inputs (water, fertilizers, and energy). Humans have to learn to live in symbiosis with soil for their survival.

CONCLUSION

In the old Roman Empire, all roads led to Rome. In the long-term survival of human society, all roads lead back to the soil.^[13] Human society must respect soil, the media that feeds the world and purifies the environment. World soils have the capacity to feed the population, provided that soils are used, improved, and restored. Judicious management of soil resources is a solution to the environmental issues (water quality and the greenhouse effect) and also to achieving global food security.

Human Society and the Planet: Soil as a Heritage

Fred P. Miller

School of Natural Resources, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Both nature and humans have left (and are still leaving) imprints on the earth's soil resources. Soil is the earth's equivalent to anatomical derma—a planetary vellum with the “signature” of pedogenic processes, such as climate, acting upon a variety of soil parent materials (e.g., sedimentary, igneous, or metamorphic bedrock; alluvium; glacial deposits; wind-blown silts or loess; and volcanic ash and lava). The morphology and character of the soils originating from these interactions are further modified by the topographic configuration of landscapes, the flora and fauna adapted to the resulting ecological niches, and the duration of these active processes. The spectrum of soils and ecosystems born of these pedogenic and ecological processes constitutes the natural resource heritage from which humankind and its civilizations are sustained. Agriculturally productive soils, occupying only a limited portion of the planetary soil resource pool, were precursors for the genesis of civilization. They are primary requisites for generating the necessary biomass to sustain more than 6 billion humans occupying this planet, with another 2 to 3+ billion projected to be here in the near future.

INTRODUCTION

The early Latin derivation of *Homo* (Latin for man) was *hemo*, meaning the earthly one; akin to the Latin word for earth or soil, namely, *humas*, and the Latin word for humans, namely, *humanus*.^[1] The history of humankind, and our ancestral *Homo* species, is the history of our relationship to the earth and its environment.^[2] Archeological evidence in many parts of the world reveals our penchant to alter the environment,^[3–5] be it to our boon or bane.^[6] Soil is a major component of the natural resource trinity (soil–sun–climate) from which humankind's sustenance is rooted. Soil is the common earthen parchment upon which humanity's cultural signatures are imprinted. Speech, tools, and fire (allowing for clustered habitation in inclement climates) formed the tripod of culture for Paleolithic man and his later counterparts.^[6] The sophistication and capability of modern tools, the development of multiple energy sources, and the increase in population have resulted in the capacity for modern civilization to alter the environment in ways, and at scales, unprecedented in human history. As early as the mid-19th century, human activity was recognized as a significant force in altering the environment.^[6–10] Even at the turn of the 20th century, geologists were calling humans the dominant geological force of the planet.^[9] Still, progress was measured in terms of our increasing control over nature, marching through the stages of our cultural evolution as if the earth was simply the stage upon which this human drama was acted out.^[9]

The impact of progressive stages of civilization on the environment and the tapping of the earth's stocks of natural

resources to sustain these civilizations were largely ignored.^[9] There were those thinkers and writers who recognized that civilization was dependent upon soil and other natural resources for its preservation, and that humankind had failed in its role as steward of the soil and natural resources heritage that sustains it and civilization itself.^[7,8,11]

HISTORICAL PERSPECTIVE

The dawn of civilization was rooted in the soil. As Bradley^[12] noted, “the fabric of human life has been woven on earthen looms. It everywhere smells of the clay.” An old saying, attributed to the Chinese, states that, “Man—despite his artistic pretensions, his sophistication, and his many accomplishments—owes his existence to a six-inch layer of topsoil and the fact that it rains.”

The domestication of plants and animals, i.e., the beginning of agriculture, occurred about 10,000 years ago^[2,5,13–17] and released the human species from its bondage to a hunting and gathering existence since its origin. Evidence of plant and animal domestication in the early Holocene has been documented on several continents.^[5,15–17] The effect of this profound and transforming revolution in human history was to increase the carrying capacity^[18] of a region and its ecosystem. Archeological evidence within the Fertile Crescent and areas around the Mediterranean suggests that their inhabitants were domesticators of animals and cultivators of the earliest founder cereals, such as einkorn wheat, emmer wheat, and barley, and founder legumes such as lentil, chick pea, pea, and bitter

vetch.^[14] This domestication of nature's provisions allowed the accumulation of surplus food supplies that underwrote major population expansion, the division of labor, which released many from the task of gathering—producing food, and the rise of cities and urban states.^[13,19]

Diamond^[20] posits that the development of agriculture was “the worst mistake in the history of the human race.” Most historians, anthropologists, and others, however, see this agricultural transformation of 10,000 years ago as “the greatest single step forward in the history of mankind”—the most momentous turn in the progress of humankind.^[13,21] In the words of Thomas Hobbes, life before agriculture was “nasty, brutish, and short.”^[21]

An axiom of agricultural geography holds that cultivation-based agriculture is predominantly located on soils derived from relatively young geologic parent materials such as alluvium, glacial deposits, loess, and volcanic ash. Soil provides the medium through which nutrient flows and energy conversions take place. Thus, it is not coincidental that early agriculture, and the civilizations that sprang from it, originated in broad alluvial flood plains and adjacent foothills such as the Tigris and Euphrates rivers (the Fertile Crescent), the Jordan Valley, the Nile River, the Indus River, the major rivers of Asia, and intermontane (alluvial) valleys of the Middle East. Similarly, the other early cultures were nurtured by agriculture rooted in soils derived from loess and other relatively young soil parent materials.^[5,9,16,22] Contemporary agricultural equivalents include the North American Corn Belt (glacial deposits and loess), the Central Valley of California (alluvium), the wheat region of the Northwestern United States (volcanic deposits), the rice cultures of Asia (alluvium), and the Chernozem-Black Soils of the Russian grain belt (glacial and loess materials).

The advent of the agricultural revolution was accompanied by increasing ecological manipulation. The development of the ox-drawn hoe, followed by the plow, occurred approximately 5000–6000 years ago throughout Mesopotamia, Egypt, and China.^[13,23,24] Then came plows of increasing sophistication and improved design, including seeder plows that simultaneously allowed the opened furrow to be planted, which is used in parts of the Middle East.^[13] These developments ratcheted up the capacity to manipulate the environment and commonly resulted in deleterious environmental impacts, with soil erosion being the Achilles heel of cultivation-based agriculture. Hillel^[13] has opined that, contrary to the prophet Isaiah, the plowshare became more destructive than the sword. Similarly, animal herding and overgrazing of hillsides exacerbated the environmental impacts of agriculture.

Another early technological innovation accompanied the advance of cultivation-based agriculture: irrigation. Early societies, cultures, and civilizations that developed in the arid and semiarid regions of the Middle East

needed to manipulate the hydrologic cycle for crop production. The earliest evidence of irrigated farming was found in the Jordan River Valley, within which, lay the ruins of the ancient city Jericho, dating back perhaps eight millennia.^[23] It is not surprising that irrigation was an early achievement, given the juxtaposition of the alluvial soils and the watercourses from which the alluvium was derived.

Canal systems were built throughout much of the Middle East to intercept portions of the adjacent river flows and distribute the water to crop fields. These elaborate irrigation networks relied on gravity flow, although there were gates and other features to accommodate the rise and fall of the rivers' seasonal discharges. Water-lifting devices, such as Archimedes' screw (tambour), and the animal-powered water wheel (sagia) were designed to lift water from irrigation canals and rivers to crop fields.^[25]

Irrigation came to be relied on to support civilizations throughout the history of Mesopotamia and much of the semiarid Middle East. These cultures are characterized as hydraulic civilizations,^[26] riverine,^[27,28] or irrigation-based civilizations.^[25] But civilizations that try to sustain themselves in these rainfall-deficient environments are vulnerable to two soil-related problems: silt and salt. As these civilizations' populations expanded, and agriculture and grazing moved further up-slope into the watersheds supplying the rivers and irrigation systems, accelerated soil erosion began its insidious gnawing away at the soil resources of the uplands. The silts and sediments carried downstream eventually flowed into the irrigation canals and networks, clogging them and reducing their effectiveness. Likewise, the river channels themselves became silt-laden, raising the riverbed, rendering the river unstable and prone to flooding the adjacent fields. Thus, in addition to tending to the agriculture and irrigation systems, intensive diking and levee building were required—the classic example being China's Yellow River.^[24] Removing this silt and diking river courses became labor intensive. Some cultures resorted to enslaving others for labor, capturing them as the spoils of conflict between nation states.

Without drainage systems and intensive water management in these water-deficient environments, irrigation caused water tables to slowly rise, exacerbated by silt clogging river channels causing the riverbed to rise. These rising water tables brought with them salts that eventually wicked to the soil surface, rendering the soils inhospitable to crop production with many soil areas becoming sterile. Coupled with invasions from other peoples, competition for water, reduced agricultural production, and internal conflicts and weaknesses, the collapse of civilizations throughout Mesopotamia and the Middle East reads like an historical casualty list in the “Graveyard of Empires,” including once-mighty Babylon itself.^[24]

The scarred and soil-denuded landscapes of this region and many areas around the Mediterranean attest to the

ravages of soil erosion caused by cropping or overgrazing the hillsides. Many structures and entire cities of these early civilizations are entombed in the sediments and salts unleashed by mismanagement of the land. It is ironic that the soil resources that were the heritage of these civilizations eventually became the materials contributing largely to the collapse and burial of these empires. Indeed, humankind had deeply etched its early history into the soil that became the heritage of subsequent civilizations.

The rocky and barren skeletal remnants of the upland landscapes in these regions stand in stark contrast to the original soil resources and vegetative cover. The lush cedars of Lebanon, once covering more than one half million hectares, were clear-cut for the ships of Phoenicia, for King Solomon's temple, to make way for agriculture, and other uses. Only four small (few hectares) remnant groves remain. Standing on Mount Nebo overlooking the Jordan Valley, the site where Moses once saw the lush land of "milk and honey," one sees a denuded and decimated land, capable of producing only a small fraction of its original potential.^[24,29] But within these degraded ecosystems is a lesson that is still valid. Those soils that were protected from erosion by terraces, and other measures are being cultivated as they had been for two or more millennia.

The Nile Valley has nurtured and sustained more than five uninterrupted millennia of civilizations.^[13,30,31] The duration of the Nile River civilizations and multiple collapses of Mesopotamian civilizations are because of the different soil and water regimes of the two riverine ecosystems. The scourges of siltation and salinization were not as severe along the Nile during its annual pulses as they were in the Tigris–Euphrates plain. Thus, the land of Egypt could remain perennially cultivated and productive, while the land of Mesopotamia suffered degradation.^[13] The building of the Aswan High Dam in the 1960s may be problematic for Egypt's agriculture as water tables are rising, requiring the country to invest in artificial drainage systems^[13] to stem the scourge of salinity to which it was so long immune.

The influence of soil on civilizations was not lost on the Greek or Roman empires. Plato offered the reason that Attica, a region in southeast Greece, in former times could support a soldiery exempt from the toil of farming: its soils, as is proved by the remnants now left, surpassed all others in fertility.^[9] The Greek poet Hesiod and Roman writers such as Virgil, Pliny, Varro, and Columella recognized the human impacts on nature and the importance of soil quality, particularly soil fertility and its conservation, to sustain civilization and its cultures.^[9]

The Book of Genesis in the Old Testament had a profound impact on the formation of conceptions about the relationship of humans to the earth. The commandment was to be fruitful and multiply and take possession of the earth. In much of western culture, humankind, by divine authority, assumed a powerful control over nature that led to

seeing its place in manipulating nature, which had been so wonderfully designed by the Creator.^[9] By the 17th century, the classical notion of a design in nature, the Old Testament ideas, and the new passion for science coalesced and provided the stimulus for the study of nature. The concept of civilization cooperating with nature began to unfold. By the 19th century, especially in the works of Marsh,^[7] it is recognized that humankind's unsteward-like manipulations of nature were upsetting its balance and harmony.^[9]

Population growth, the progressing of civilization, and increased pressure on the environment do not necessarily have to lead to accelerated environmental damage, although most of human history has proven otherwise. As Butzer^[32] noted, we can learn much about the environmental successes and failures through the study of human history and the lessons of our human heritage encoded in the settlement and land use histories.

CONTEMPORARY PERSPECTIVE

More than two centuries ago, Malthus^[33] recognized the decreased "power of the land" resulting from human-induced land degradation. During the 18th century, European powers were vying for dominance, control, and settlement of the North American continent. Settlement of the continent was accompanied by the same exploitive behavior that occurred throughout the history. It was during this time that Marsh^[7] and others^[6,8–10] recognized the significance of human impacts on the environment and the historical arrogance toward nature.^[34–37] White^[34] argued that this attitude is dominant in western traditions stemming from westerners' religious beliefs. But Tuan^[37] argued that the tendency toward environmental degradation and the desire to maximize one's well-being characterize all human existence. White^[34] stated that "the emergence in widespread practice of the Baconian creed that scientific knowledge means technological power over nature can scarcely be dated before about 1850. Its acceptance as a normal pattern of action may mark the greatest event in human history since the invention of agriculture, and perhaps in nonhuman terrestrial history as well."

The early American settlements became the catalyst for mass migrations of Europeans to this new land, migrations that lasted for three centuries. The vast and resource-rich continent that lay before these settlers, and the speed with which it was populated, are unprecedented in history.^[29] As a testimonial to the resources that these settlers inherited, the dense forests were considered an obstacle to agriculture even though they were utilized for fuel and timber. The volume of this timber resource was so large that the center of the commercial lumbering industry did not move beyond western New York until after 1850.^[36] Between 1850 and 1910, American farmers cleared more forest than in the previous 250 years—about 77 million hectares

(190 million acres), equivalent to clearing 35 square kilometers (13.6 square miles) every day for 60 years.^[38]

During these westward migrations, the vastness of the resource base, and the open and cheap land areas available to the west, became the settler's talisman, and worked against a psychology of permanence.^[36] The knowledge that these western lands were still available tended to salve the anxiety of failure and was not conducive to fostering a conservation ethic or to promoting a sense of stability. So plentiful was the North American natural resource heritage that its vastness betrayed its vulnerability.

To illustrate this impermanence syndrome and the environmental impact of its perpetrators, Trimble^[39] cited one wit of the late 1830s, who summarized the situation in the southern Piedmont by noting that "the scratching farmer's cares and anxieties are only relieved by his land soon washing away. As that goes down the rivers, he goes over the mountains." Gray^[40] also pointed out the tendency to deplete land and then migrate west by stating that, "Over the upland soils from Virginia to Texas the wave of migration passed like a devastating scourge. Especially in the rolling piedmont lands, the planting of corn and cotton in hill and drill hastened erosion, leaving the hillsides gullied and bare." An 1853 appraisal of Laurens County, South Carolina^[39] was written in apocalyptic prose, "The destroying angel has visited these once fair forests and limpid streams. The farms, the fields are washed and worn into unsightly gullies and barren slopes—everything everywhere betrays improvident and reckless management."

As northern and southern migrations into the semiarid portion of the new nation continued, the exploitation of the soil resources under the onslaught of these migrations was exacerbated by another human imprint on the soil—the great Dust Bowl era. The vast expanse of prairie encountered by the western migration was unparalleled in the history of human settlements. The European background of the encroaching settlers, and any experience that may have been acquired in the humid east, left unprepared for those who first entered the tallgrass prairie and then the semiarid shortgrass region. The latter ecosystem proved the undoing of those who broke the sod. Tempted by their tradition, lured by the bait of immediate profits, and encouraged by financial and industrial interests,^[36] the settlers' breaking of the sod in this region, coupled with the vagaries of its climate, triggered one of the great ecological disasters of human history. On May 12, 1934, the droughts common to this marginal-cropping region resulted in the first of many dust storms. It was a tragic event in American history that scarred both the land and its people. The impacts of this Dust Bowl were felt from Texas to the Dakotas, damaging some 60–80 million hectares of land.^[41]

The commentary of various witnesses to the erosive demise of many landscapes provides a unique description

of ecological devastation as seen through the eyes of those who experienced it personally. Such accounts echo a common concern, if not resignation, among those who wrote about it. Recorded in these accounts is an intensity of feeling and despair reserved only to those who become personally engulfed in an ecological catastrophe where its shock and impact have not been tempered by either time, healing of the landscape, or by the muffled accounts of historians.

Sears^[36] quotes the owner of a large tract in the short-grass country that had been plowed for wheat in the 1930s, "We're through. It's worse than the papers say. Our fences are buried, the house is hidden to the eaves, and our pasture which was kept from blowing by the grass, has been buried and is worthless now. We see what a mistake it was to plow up all that land, but it's too late to do anything about it." Others were not so articulate about the problem. They simply packed their few belongings and headed west, much as they and their predecessors had done when the water-induced erosion to the east had rendered the land scarred and unyielding. These hardy but tragic people became the human pulp for Steinbeck's *The Grapes of Wrath*. They left behind the scars of a squandered heritage: a damaged ecosystem totaling many tens of millions of hectares.^[42]

In response to this ecological disaster, a new federal agency was formed in 1933, the Soil Erosion Service, which became the Soil Conservation Service in 1935. Soil conservation became a national policy, although its implementation was based on voluntary participation of land owner-operators baited with the incentives of technical and financial assistance. As the necessity to manage ecosystems more holistically became understood, and the concept of ecological sustainability entered the global lexicon, agencies, and institutions took a more comprehensive view of ecosystem management. During the 1990s, the Soil Conservation Service was renamed the Natural Resources Conservation Service, and many federal and state agencies adopted sustainable ecosystem management as their mantra.

CONCLUSION

Is modern society, with all of its technological sophistication, as bound by the limits of its environmental heritage as were previous societies and cultures? Or do science and technology allow humankind to pursue its prerogatives, unhindered from any obligation for stewardship and sustainable management of its natural resources and soil heritage? The answer to these questions is a resounding "no." The laws of nature and thermodynamics preclude any shortcuts to sustaining civilizations without the sustainable management of the ecosystems and ecological processes that undergird our sustenance and well-being. Even though humankind has

opted out of the tyranny of natural selection,^[43] the inextricable interconnectedness of the environment and human well-being requires our understanding of the global environment. The sustainability of the biosphere is now seen to be inseparably bound to issues of economic development, social equity, and international peace and security.^[44] One of the major challenges is to continue to ratchet up the carrying capacity of our soil heritage while sustaining its inherent productive qualities and minimizing leakages of production inputs. Humans have already expanded the carrying capacity of their agricultural ecosystems a 1000-fold^[18] through such innovations as genetic manipulation of plants and animals and the development of synthetic nitrogen. There are only certain areas of our soil heritage that can accommodate the intensity of these ecological manipulations productively and sustainably. Our soil heritage is as vital to modern civilization as it was to our ancestral hunter-gatherer kin. As Smil^[18] has noted, “our ‘postmodern’ civilization would do quite well without computers and software, without ATMs and the WWW but it would disintegrate in a matter of years without synthetic nitrogen fertilizers, and it would collapse in a matter of months without thriving (soil) bacteria. Our first duty is to take care of these true essentials.” Modern civilization is not less dependent upon the soil and ecological heritage than its foraging and pastoral fore-bearers. The causes of the earth’s major environmental problems are rooted in human behavior. Thus, our greatest challenge is to understand the limits and vulnerability of our soil and natural resources heritage and behave accordingly.

Abstract

Transport of chemicals and flow of water in soil depend on, among other things, the soil's hydraulic properties. One of these hydraulic properties is the hydraulic conductivity function. In general terms, one could say that the hydraulic conductivity (m/sec) is a measure of the ability of a soil to conduct water.

BACKGROUND INFORMATION

The flow of liquid water through soil is generally viscous and laminar, i.e., non-turbulent. This is because of the small sizes of the pores in which the water movement takes place. Under these conditions, the water flux density q (m/sec, vector quantity) is proportional to the driving force, which is equal to the negative of the hydraulic head gradient ∇H (dimensionless, vector quantity). The magnitude of q is defined as the volume of water V (m³) passing through a cross-sectional area of soil A (m²) during time t (sec). The hydraulic head H (m, scalar) is the potential energy (J) of water on a weight (N) basis. It incorporates the influences of forces such as gravity, pressure, and capillarity. The proportionality factor relating the flux density to the driving force is called the hydraulic conductivity K (m/sec, tensor). In mathematical form, the flux density can be expressed as

$$q = -K \cdot \nabla H \quad (1)$$

K varies from soil to soil and even within the given soil, as it depends on soil properties such as fineness, clay content, solid particle orientation, organic matter content, and water content. Eq. 1 was formulated by the French engineer Darcy^[1] and is often referred to as Darcy's law. As the hydraulic head H (m) has units of length, the hydraulic gradient, ∇H , is dimensionless. Thus, the units for the water flux density and the hydraulic conductivity are the same, i.e., meters per second. Other, less frequently used units for the hydraulic potential result in different units of the hydraulic conductivity. The term hydraulic conductivity should not be confused with permeability (m²) as the former includes

liquid and porous medium properties, while the latter should only reflect porous medium properties.

In general, the proportionality relation, Eq. 1, between the two vectors q and ∇H is tensorial, which means that K needs to be expressed as a matrix. This is necessary when the soil's structure forces water to flow in a direction different from that of the hydraulic head gradient. These soils, called anisotropic, occur frequently in nature. Most soils resulting from sedimentary processes exhibit preferential flow pathways, often perpendicular to the deposition direction that occurred during soil formation. Also, charged clay particles often arrange themselves in sheet-like configurations that create anisotropy. Although important, consideration of the soil's anisotropy involves complications that are beyond the scope of this entry, and the reader is referred to the literature for further information.^[2]

If the soil possesses the same conductive properties in all directions, it is called isotropic. In this case, the water flow takes place parallel to and in the opposite direction of the hydraulic head gradient, and K can be considered a scalar. For a simple application of Darcy's law (Eq. 1) to an isotropic soil, such as a well-packed sand, let us consider a horizontal soil column of constant cross-sectional area subjected to a hydraulic head gradient that is established by two constant-level water reservoirs (Fig. 1). The column is located beneath the water levels, and the soil's entire pore volume is filled with water. The hydraulic head at each end of the column is then simply equal to the water levels H_1 and H_2 in the water reservoirs, as measured with respect to an arbitrary elevation reference. The hydraulic head gradient, uniform throughout the soil column, is equal to the difference between the hydraulic head values H_1 and H_2 divided by the length of the column L , i.e.:

Fig. 1 Schematic diagram for application of Darcy's law.

$$\nabla H = \frac{H_2 - H_1}{L} \quad (2)$$

which is negative. This implies that water flows from reservoir 1 to reservoir 2, i.e., in the direction of decreasing hydraulic head values. For a soil with hydraulic conductivity K , the magnitude of the water flux density (q , scalar) can then be calculated from

$$q = \frac{V}{At} = K \left| \frac{H_2 - H_1}{L} \right| \quad (3)$$

As an example calculation, consider a 1 m long column ($L = 1$ m) with a cross-sectional area $A = 10^{-2}$ m², containing a water-saturated sand with a hydraulic conductivity value $K = 10^{-4}$ m/sec. The water level in the left reservoir is 0.06 m higher than in the right reservoir. This results in a water flux density of 6×10^{-6} m/sec, oriented from left to right, and hence a discharge rate, V/t , of 6×10^{-8} m³/sec, i.e., 60 μ l of water crosses any section of the column in 1 second. The value for the water flux density, which is expressed as a velocity and is sometimes referred to as the Darcy flux or Darcy velocity, should not be mistaken for the average velocity of the water in the pores, known as the seepage or pore water velocity v (m/sec, vector quantity). The difference between the water flux density and the pore water velocity is because of the fact that water occupies only a limited fraction of the soil's total volume. In the case of a water-saturated soil, the soil's volumetric water content, θ , is equal to the porosity n of the soil, i.e., the ratio of the pore volume and the soil's bulk volume. Consequently, water flows only through the fraction nA of a cross-section with area A . The true water velocity, or the pore water velocity, is therefore^[3]

$$v = \frac{q}{n} \quad (4)$$

Assuming a porosity $n = 0.3$, the average pore water velocity or seepage velocity of the water in the column is 2×10^{-5} m/sec or 7.2 cm/hr.

Darcy's law can also be applied to unsaturated soils, i.e., soils containing water and air.^[4] In this case, the soil's hydraulic conductivity is a function of its volumetric water content θ (defined as the volume of water per unit volume of bulk soil), and the seepage velocity is expressed as

$$v = \frac{q}{\theta} \quad (5)$$

Hydraulic conductivity is difficult to measure *in situ*, especially when the influence of θ needs to be quantified. Consequently, a great deal of research has been conducted to estimate K from more easily available soil data. Most of these approaches rely on assuming a certain geometry for the soil pore space, the simplest of them being a bundle of circular capillary tubes, in which the well-defined Hagen–Poiseuille flow occurs. Pioneering work in this area was conducted by Kozeny^[5] and later by Carman,^[6] whose work led to a formula for estimating K of saturated soils. By applying the Kozeny–Carman concepts, it can be shown that saturated hydraulic conductivity is approximately proportional to the square of a mean soil particle diameter. Hence, if the mean particle diameter for a given soil is twice as small as for another soil, its saturated K value will be four times smaller. Notably, clayey soils are often very restrictive to water flow and have saturated K values ranging from 10^{-6} to 10^{-9} m/sec. Sandy soils, on the other hand, offer much less resistance to water flow and have saturated K values in the range of 10^{-4} to 10^{-5} m/sec. Saturated K values (K_{sat}) for various soils are listed based on soil texture in Table 1. Although the Kozeny–Carman theory provides good results for sandy, fully saturated porous media, its application to soil science is somewhat limited, because the predictions for fine-textured or structured soils are usually not very good and most soils contain entrapped air when

Table 1 Saturated hydraulic conductivity values (K_{sat}) for various soils by soil texture.

Soil texture	Siltfraction	Clayfraction	$K_{\text{sat}} \times 10^5$ (m/sec)
Sand	0.05	0.05	1.4 (0.70–7) ^a
Loamy sand	0.10	0.07	1.0 ^b or 1.9 ^c
Sandy loam	0.25	0.10	0.7 (0.4–2) ^a

“saturated.” For this reason, soil scientists sometimes use the term satiated θ , with its corresponding satiated K . Under unsaturated conditions, in the presence of a continuous air phase, capillary forces cause the water to occupy the smaller soil pores, while air invades the larger pores. Because the ability to conduct water decreases with decreasing pore size, the unsaturated hydraulic conductivity decreases rapidly with decreasing θ . Corey^[9] observed that in sedimentary rocks, K is often approximately proportional to the fourth power of θ . A twofold reduction in θ will therefore result in a 16-fold decrease in K . In fact, K values easily decrease five orders of magnitude when θ decreases from its satiated to its residual value. Besides the Brooks–Corey type of empirical relationship between K and θ , more elaborate techniques are often used to estimate unsaturated K values from water retention data. Most of these techniques assume a certain form for the soil water retention curve and use the parameters associated with the water retention relationship to express the hydraulic conductivity as a function of water content or matric head. The most commonly used models are those of Brooks and Corey^[10] and van Genuchten,^[11] using the capillary models of Burdine^[12] and Mualem,^[13] which are extensions of the Kozeny–Carman theory. Based on the pore size distribution factor of their water retention function, λ , Brooks and Corey^[10] derived

$$K_{\text{rel}} = \frac{K}{K_{\text{sat}}} = \left(\frac{h_d}{h_m} \right)^\eta \quad (6)$$

where K_{rel} and K_{sat} are the relative and saturated hydraulic conductivity values, respectively, h_m (m) is the matric head, and h_d (m) is the displacement head, i.e., the value for h_m at which water in a saturated soil is first displaced by air, and

$$\eta = 2 + 3\lambda$$

Based on the dimensionless constant m , appearing in his functional relationship of the water retention curve, van Genuchten^[11] derived

$$K_{\text{rel}} = S_e^{1/2} \left[1 - (1 - S_e^{1/m}) \right]^2 \quad (7)$$

where the effective saturation was

$$S_e = (\theta - \theta_r) / (\theta_s - \theta_r)$$

The subscripts s and r refer to saturation and residual, respectively. It was found that the applicability of these methods, based on retention information, is greatly increased when at least one value for K at a θ different from saturation (mostly satiated) is measured. This is because of the fact that it is difficult to extrapolate the soil’s conductive behavior from the situation near water saturation, where most water is conducted through macropores or fissures, which barely influence the soil’s water retention relationship. In addition, more detailed information regarding the

above and other relationships can be found in Kosugi et al.^[14] Techniques for direct or indirect determinations of saturated and/or unsaturated hydraulic conductivity values are described in Reynolds and Elrick [constant head on soil cores, falling head on soil cores, measurement techniques above the water table, pressure (single-ring) infiltrometer, and constant head well permeameter]; Booltink and Bouma (steady flow/piezometers and suction crust infiltrometer); Youngs (double/multiple ring infiltrometer); Amoozegar (auger hole and piezometer); Scotter and Clothier (one-dimensional infiltration equations, horizontal absorption, 3-D infiltration); Corey (long column); Nimmo et al. (steady-state centrifuge); Arya (wind and hot air methods, plane of zero flux); Vachaud and Dane (instantaneous profile); Parkin and Kachanoski (constant flux vertical TDR); and Hopmans et al. (inverse methods).^[14]

Complementary estimation of hydraulic conductivity can be obtained through statistical, empirical analysis (Nimmo^[14]). When numerous samples of known hydraulic conductivity have been taken over an area presenting some general characteristics, the hydraulic conductivity of a new sample can be roughly estimated from more easily available data. Particle-size data are often chosen^[15,16] because they are routinely obtained by sedimentation analysis, and because hydraulic conductivity is very much influenced by the amounts of clay contained in the soil.

Because hydraulic conductivity is very much dependent on soil structure, i.e., on the occurrence of aggregates and/or cracks, either because of natural causes (soil erosion, shrink/swell, and biological activity) or human factors (tillage and compaction), its value can vary greatly within short distances in the field. Microbial and fungal activity can also have quantitative effects on the hydraulic conductivity by pore clogging, as does temperature by its influence on the water viscosity.^[17] Finally, soil water chemistry influences the hydraulic conductivity of soils containing shrink/swell clay minerals.^[18] If the soil water does not contain sufficient quantities of mainly polyvalent cations, it can cause the clay to swell or even destroy the soil structure. This can greatly reduce the soil’s conductive properties to water. As a result of these chemical, biological, and human factors, the hydraulic conductivity of a soil is likely to vary greatly not only over distance but also over time.

CONCLUSION

One of the governing properties determining flow rates of water is the hydraulic conductivity, the other one being the hydraulic head gradient. For soils saturated with water the hydraulic conductivity, referred to as saturated hydraulic conductivity, reaches its maximum value. The hydraulic conductivity value decreases rapidly with decreasing water content. The relationship between hydraulic conductivity and water content varies from soil to soil and may be even different for the same soil at different locations.

Hydrologic Cycle

Keith R.J. Smettem

*Soil Science and Plant Nutrition, University of Western Australia, Nedlands,
Western Australia, Australia*

Abstract

The role of soils in the hydrological cycle becomes progressively more complex, as time and space scales are reduced. The requirement for detailed soils information is essential for understanding runoff generation and preferential flow processes at local scale. However, for understanding annual or seasonal hydrological trends at large catchment or regional scales, information on soil texture and soil depth can provide sufficient information for estimating the soil water storage capacity.

INTRODUCTION

Climate, soil, vegetation, and topography all play important roles in maintaining the water balance of catchments.^[1] Changes in even one of these factors will affect the hydrological response to rainfall, in terms of both water quality and quantity. At a broad regional scale, Milly^[2] showed that the annual water balance is controlled primarily by climate (as measured by a simple climatic index of dryness, given by the ratio of annual potential evaporation to annual precipitation) and to a lesser extent by the soil storage capacity of the landscape. Reggiani et al.^[3] also show that at catchment scale, total annual evaporation and runoff are controlled by climate (through a dryness index) and soil type. Topographic or landscape factors only become significant when consideration is given to partitioning total runoff into surface and subsurface contributions.^[3]

A REGIONAL SCALE PERSPECTIVE FOR LARGE SPACE AND TIME SCALES

At large space and annual time scales, the role of the soil in the hydrological cycle is, therefore, primarily as a transient store for water. At continental scales, Manabe^[4] simulated the water balance using a simple bucket representing soil water storage and an evaporative threshold. Milly and Dunne^[5] presented similar results showing that at continental and regional scales, simple lumped storage representation of surface hydrology proved to be sufficient to capture the salient features of catchment behavior.

A LOCAL PERSPECTIVE AT SMALLER SPACE AND TIME SCALES

Soils and Runoff Generation Processes

When spatial and/or temporal scales of interest are reduced, consideration must be given to a more detailed

understanding of processes leading to runoff generation and groundwater response. In particular, water flux rates over and through the soil assume increasing importance. Surface runoff may be generated as a “top-down” or “bottom-up” process. The “top-down” process is referred to as infiltration excess runoff and occurs when the intensity of rainfall exceeds the rate of infiltration at the soil surface. The “bottom-up” process is referred to as “saturation excess” and occurs when initially unsaturated soil water stores are filled to overflowing so that additional rainfall simply runs off the saturated area.

Dynamics of Runoff Source Areas

The area of soil contributing to saturation excess runoff from a catchment is temporally dynamic, increasing as a storm progresses and diminishing thereafter. This “variable source area”^[6] for runoff generation is dependent on storm characteristics (duration and volume), soil type, and position in the landscape. Topographic indices of wetness have long been used to identify likely runoff producing areas^[7] because the general tendency of water to flow downhill is amenable to macroscopic conceptualization. Soils tend to remain wetter as the upslope contributing area increases, particularly in areas of topographic convergence,^[8] so it is perhaps not surprising to find that soils close to water-courses tend to saturate first during rainfall. The concept of an upslope contributing area for saturation-excess flow is most readily applied to soils that are shallow, relative to the hillslope scale, under conditions that are wet enough to generate lateral downslope saturated flow through the soil. Lateral downslope saturated flow can of course also be generated over impeding layers in the soil profile.

Predicting Infiltration Excess Runoff

Prediction of infiltration excess runoff requires knowledge of particular soil hydraulic properties that characterize infiltration behavior and the rainfall rate must be specified at

short timesteps (typically minutes). One typical quasi-analytic equation for predicting the time to incipient ponding (the time at which a free water film first appears on the soil surface) is^[9]

$$t_p = M(S^2/K_s R_p) \ln\{R(t_p)/[R(t_p) - K_s]\} \quad (1)$$

where S is the sorptivity ($LT^{-0.5}$), K_s is the saturated hydraulic conductivity (LT^{-1}), $R(t_p)$ is the rainfall rate at incipient ponding (LT^{-1}), R_p is the mean rainfall rate up to ponding, and M is a constant, generally set to 0.55.

The sorptivity^[10] is a characteristic of the soil's capillarity properties and varies with soil texture, structure, and initial water content. The saturated hydraulic conductivity is dependent upon soil texture and can be significantly affected by the degree of soil structure development. Both hydraulic properties can exhibit a high degree of spatial variability, and frequency distributions of saturated hydraulic conductivity are often log-normal.^[11] Rawls et al.^[12] provide summary data on saturated hydraulic conductivity for each of the major United States Department Agency textural classes and point out that soil structure effects can override any differences between texture classes.

Factors Affecting the Time of Runoff Generation

The time at which surface runoff commences after incipient ponding depends on a number of complex interacting factors. Surface microtopography is particularly important because it controls the amount of surface (detention) storage that can occur. Flow concentration into rills can have a major effect on reducing effective wetted areas subject to infiltration after rainfall ceases. If the saturated hydraulic conductivity increases downslope then this in turn can have a major impact on runoff peaks, volumes, and the time to peak runoff.^[13]

Over time scales that are typically of interest in process hydrology (1 year or less), soil texture can be regarded as a fixed property in space and therefore patterns of textural distribution within catchments are amenable to mapping. Maps of soil hydraulic properties can then be derived from this basic information using indirect functional relations.^[14,15] In contrast, soil structure arising from biotic or pedogenic activity can be highly variable temporally, particularly if the land surface is subjected to agronomic manipulation. Agronomic practices that expose soil to the beating action of raindrops often result in the destruction of surface soil structure and the consequent formation of surface skins or seals with low hydraulic conductivity. Physically, within the seal layer, both porosity and pore size distribution are altered. Large conducting pores are destroyed, and the total porosity is reduced. These changes lead to greatly enhanced surface runoff and possible removal of soil by water erosion.

The effects of soil structure on hydrologic response are often incorporated within descriptions of land use and

treatment. Although land use and treatment are not primary physical variables, they are easy to map and have a long history of use as classificatory discriminators of runoff behavior. For example, the SCS curve number procedure^[16] represents the soil-cover complex and a five-day antecedent rainfall that is referenced to dry, normal, or wet conditions. This approach is also to be found in well known hydrological models such as CREAMS.^[17]

Partial Wetting and Other Preferential Flow Processes

Soils that exhibit hydrophobic (nonwetting) behavior can yield considerably more surface runoff under dry antecedent conditions than would be predicted from a consideration of soil texture alone. Non-wetting behavior can also generate "finger flow," which is a form of physical non-equilibrium leading to preferential wetting of only a small fraction of the total soil volume. Preferential flow can also occur through soil macropores that are connected to a source of free water or by funnel-type flow due to layering structures in sandy soils.^[18]

Identification of soils and field conditions that result in preferential flow is the subject of considerable research effort because of the potential contamination risk to groundwater systems posed by the rapid movement of dissolved chemicals through the unsaturated zone.

CONCLUSION

The role of soils in the hydrological cycle becomes progressively more complex, as time and space scales are reduced. The requirement for detailed soils information is essential for understanding runoff generation and preferential flow processes at local scale. However, for understanding annual or seasonal hydrological trends at large catchment or regional scales, information on soil texture and soil depth can provide sufficient information for estimating the soil water storage capacity.

Hydropedology

Henry Lin

Department of Crop and Soil Sciences, Pennsylvania State University, University Park, Pennsylvania, U.S.A.

Abstract

Hydropedology is an intertwined branch of soil science and hydrology that embraces a systems and multiscale approach to the study of soil–water–landscape relationships across space and time. This emerging interdisciplinary science seeks to understand the complex and dynamic behavior and the distribution of soil–water interactions in contact with mineral and biological materials in the near-surface terrestrial environment. This entry provides a brief overview of its basic concept, characteristics, fundamental issues, and diverse applications.

INTRODUCTION

Hydropedology integrates pedology, hydrology, geomorphology, and other related bio- and geosciences to study soil–water–landscape relationships across space and time, emphasizing the connection between the pedon and the landscape paradigms (Fig. 1).^[1] It aims to understand pedological controls on hydrologic processes and properties as well as hydrologic impacts on soil formation and functions.^[2–4] Two fundamental questions of hydropedology are the following^[5]:

How do soil architecture and the distribution of soils over the landscape exert a first-order control on hydrologic processes (and associated biogeochemical and ecological dynamics) across spatiotemporal scales?

How does landscape water (and the associated transport of energy, sediment, chemicals, and biomaterials by flowing water) influence soil genesis, evolution, variability, and functions?

Landscape water encompasses the source, storage, availability, flux, pathway, residence time, and distribution of water in the near-surface terrestrial environment. Although source, storage, availability, and flux of water in the soil have been studied extensively in the past, attention to flow pathways (especially flow networks), residence times (ages of water), and spatiotemporal patterns of flow dynamics (and its underlying organizing principles) has been much limited.^[4,6]

Water flux into and through the soil and over the landscape is the essence of life, which resembles the way blood circulates in a human body.^[7] The interactions between soil and water are so intimate and complex that they cannot be effectively studied in a piecemeal manner; rather, they require a systems and multiscale approach. It is, in this spirit, hydropedology has emerged.^[2–5]

CHARACTERISTICS OF HYDROPEDOLOGY

Two general characteristics of hydropedology can be highlighted as follows:

1. Hydropedology emphasizes *in situ* soils in the landscape, where distinct pedogenic features (e.g., structure, horizonation, and redox feature), soil–landscape relationships (e.g., catena, soil pattern, and soil map), environmental variables (e.g., climate, landforms, and organisms), and anthropogenic impacts (e.g., land use and management) prevail and interact, leading to a complex and dynamic control on the hydrologic cycle and ecosystem functions. Hydropedology attempts to link the past of soils (i.e., soil formation and evolution as a record of the past environment) to the present and future of soils (i.e., soil changes under existing land use and future climate). Hydrology offers an attractive potential to quantify soil-forming processes, because all natural soil-forming factors affect and are affected by hydrology. Water is also key to quantify soil functions; once water regime is characterized, soil physical, chemical, and biological functions can be added as they strongly depend on the water regime and on interactive processes with the soil.
2. Hydropedology promotes a unification of soil forms (i.e., soil architectures and maps) and soil functions rather than mapping soils without considering specific soil functions or modeling soil functions without incorporating soil architectures and soil–landscape patterns. A new era of soil research must be based on soil architecture (i.e., the entirety of how the soil is structured, which encompasses solid components, pore space, and their interfaces). This will improve the prediction of flow (and reaction) pathways, patterns, and residence times but require innovative techniques for improved

Fig. 1 Hydropedology connects the pedon and the landscape paradigms through linking phenomena occurring at the microscopic (e.g., pores and aggregates) to mesoscopic (e.g., pedons and catenae), macroscopic (e.g., watersheds and regional), and megascopic (e.g., continental and global) scales. There are strong links between ubiquitous heterogeneity and diverse preferential flow in natural soils and landscapes across scales.

Source: The lower right diagram of a hillslope is modified from Atkinson.^[1]

quantification of soil architecture and related flow dynamics across scales (especially *in situ* non-invasively and with high spatial and temporal resolution). New ways of characterizing and mapping soils in the landscape are also needed, including the identification and delineation of soil–landscape units with similar pedological and hydrologic functions.^[8]

FUNDAMENTAL ISSUES

Fundamental scientific issues of hydropedology, at this stage of its development, are centered on the following four categories^[3,5]:

1. *Soil structure and horizonation vs. in situ water flow and chemical transport*: hydropedology emphasizes quantitative soil architecture of field soils and its links to preferential flow across scales.
2. *Soil catena and distribution pattern vs. water movement over the landscape*: hydropedology focuses on

quantitative relationships between the distribution of field soils and their surrounding landscape and the impacts of such relationships on hydrologic (and related biogeochemical and ecological) processes.

3. *Soil morphology and pedogenesis vs. soil hydrology and soil change*: hydropedology utilizes quantitative soil hydromorphology as a signature of soil hydrology and uses the soil as valuable records of past environmental change over time.
4. *Soil functions and maps vs. carriers of soil quality and soil–landscape heterogeneity*: hydropedology promotes quantitative delineation of functional soil units in the landscape as well as precision soil–landscape mapping for various applications.

APPLICATIONS AND LINKS TO OTHER DISCIPLINES

Hydropedology contributes to a variety of environmental, ecological, agricultural, and natural resource issues of

societal importance, including water quality, hydrologic fluxes, soil quality, nutrient cycling, landscape processes, watershed management, contaminant fate, waste disposal, precision agriculture, climate change, and ecosystem functions. In the integrated studies of the earth's critical zone that ranges from the vegetation top to the aquifer bottom,^[5,9] hydropedology is linked to a number of related disciplines to address critical interactions and feedback mechanisms, as highlighted in the following (Fig. 2):

- There is a clear linkage between aboveground ecohydrology and belowground hydropedology in various ecosystems. For example, Li et al.^[10] demonstrated important connection between aboveground stemflow and belowground preferential flow in desert shrubs, revealing the importance of the interrelationships between hydropedology and ecohydrology and how soil moisture and plant growth influence each other.
- The integration of hydropedology and hydrogeology provides a more holistic way of predicting subsurface flow and transport from the ground surface all the way down to the aquifer. The bridging of pedon-scale observations and landscape-scale phenomena, with appropriate incorporation of soil structure into preferential flow modeling, could expedite solutions to many problems of non-point source pollution and groundwater contamination.
- Coupling hydropedology with (hydro)geophysics is an area that has not been well explored. Many questions remain regarding how best to transfer geophysical signals measured to hydrologic properties of interest. One way to get around this inversion problem is to insert pedological insights (e.g., soil types, layers, and structural phases) to help constrain or zone the geophysical inversion. Time-lapse geophysical imaging can also be used to reveal subsurface heterogeneity and complex preferential flow dynamics.
- Linking hydropedology with hydrogeomorphology provides an integrated research and application in the areas of landscape and hillslope evolution, spatial and temporal patterns of water and sediment dynamics in complex terrain, and the assessment of distributed land management practices on soil and water resources and their interactions with natural hazards. Land management decisions concerning where and when specific operations can take place are strongly influenced by spatiotemporal, hydrogeomorphic, and hydropedologic relations, as are sediment and landslide hazards.
- The linkage between hydropedology and hydrometeorology includes issues related to soil moisture and global climate change, soil carbon sequestration, greenhouse gas emission from soils, and remote sensing of soil climate.^[11]
- Coupling hydropedology and biogeochemistry can help the identification of hot or cold spots and hot or cold

Fig. 2 Relationship of hydropedology with other related disciplines, where pedology, hydrology, and soil physics serve as the three cornerstones for hydropedology.

- moments of biogeochemical cycles in different ecosystems, which are often triggered by soil hydrologic conditions.^[12,13] This is important to subsurface microbial activities, contaminant remediation, ecological health and diversity, and environmental quality in general.
- The study of paleohydropedology (Paleosols and paleohydrology) has demonstrated valuable historical records of the past environment and ancient landscape–soil–water–ecosystem–climate relationships.^[14]
 - The connection between hydropedology and land use planning is linked to environmental regulation and policy, because how natural soils “throb” upon precipitation inputs under various climates offers clues as to “what” best can be done and “where” has the lowest risks and the greatest opportunities for land use and management.^[7]
 - Hydropedology contributes important knowledge to sustainable development using “soft,” ecological engineering that aims at utilizing natural systems to provide needed services, including stormwater management, urban drainage, and hazard mitigation. In the meantime, communications with engineers and the sociopolitical process are critical for realizing these goals.
 - The emerging critical zone science^[5,9] provides a new interdisciplinary platform for the holistic studies of water with soil, rock, air, and biotic resources in the near-surface terrestrial environment. The critical zone is the most heterogeneous and complex region of the earth that requires contributions from many disciplines including hydropedology.^[5]
 - Knowledge of the soil and its forming processes has unique contribution to extraterrestrial explorations in search of liquid water^[15] and life and to developing advanced life support systems used in space exploration. For example, how the weathering engine on Mars has transformed the protolith into various soils could shed light on the role of water (and other soil-forming factors such as climate) in the genesis and evolution of Martian soils.

Hydrophobic and Hydrophilic Compounds

Tomas Simon

Department of Plant Nutrition, Crop Research Institute, Prague, Czech Republic

Abstract

Soil organic matter (SOM) plays a key role in the soil quality. Besides carbon and nitrogen content, SOM composition can also be defined as the amount of functional groups (i.e., hydrophobic and hydrophilic groups) and their spatial arrangement in SOM at the molecular scale. The SOM functional groups are responsible for the chemical reactivity and sorptivity of SOM. The importance of SOM hydrophobic and hydrophilic compounds for soil hydrophobicity and related spectroscopic techniques used for the determination of these SOM constituents is described in this entry. Fourier transform infrared (FTIR) spectroscopy of humic substances or bulk soil samples can distinguish hydrophobic and hydrophilic functional groups in FTIR spectra and may be useful for analyzing SOM quality and to improve interpretations of its physicochemical properties.

INTRODUCTION

Soil organic matter (SOM) is a complex material consisting of plant biopolymers, animal and microbial residues, and humic substances. It plays a key role in soil quality through moderating biological, physical, and chemical properties of soils. It contributes to the stability of soil aggregates and provides energy and body building constituents for the soil biota. The SOM also affects many other soil characteristics such as soil porosity, water-holding capacity, hydraulic conductivity and detoxication of pollutants, erosion, etc.

The SOM composition depends on soil type and land management. In arable soils, both the amount and composition of the SOM depend on the organic matter input from organic manuring, crop, and root biomass.^[1] The SOM is also related to crop rotation including cultivation of leguminous crops.

While the SOM quantity is mostly determined as the total organic carbon (C) or nitrogen (N) content in the top soil, soil quality is characterized using various methods especially determining labile components of the SOM (light fractions, water extractable fractions, dissolved organic matter, microbial biomass C, etc.).^[2] As large fraction of the SOM in many arable soils is assumed to be relatively inert, analysis of total SOM is not sensitive to assessing the management effect. On the contrary, determination of labile water soluble soil organic fractions with relatively fast turnover rates may reflect short-term effects of crop fertilization and rotation.

However, SOM contains not only C but also a number of heteroatoms, which characterize SOM composition and interaction with mineral surface. The SOM composition,

therefore, can be defined as the amount of functional groups (i.e., carboxylic and hydroxylic groups) and their spatial arrangement in SOM at the molecular scale. The spatial arrangement of the hydrophobic components within SOM strongly affects wettability, which is dependent on the SOM–mineral interactions. The SOM functional groups are responsible for the chemical reactivity and sorptivity of the SOM (e.g., hydrophobicity or cation exchange capacity).^[3]

The hydrophobicity of SOM is caused, essentially, by aliphatic C–H units present in methyl, methylene, and methine groups. These substances may be released from a range of plants, decaying SOM, soil fauna, and microorganisms. The number of aliphatic C–H units control the water affinity that influences resistance to microbial degradation, the rate of wetting, and adsorption processes. Hydrophobic organic constituents may be a primary cause of soil repellency; hydrophilic constituents affect soil wettability.^[4] Soil wettability depends, therefore, on composition and spatial arrangement of different hydrophobic constituents.

It may also be assumed for SOM that the ratio between hydrophilic and hydrophobic functional groups (e.g., C=O/CH ratio) could be used as an index soil's wettability. Most soils are neither completely hydrophilic nor hydrophobic. However, they exhibit a subcritical level of water repellence.^[5] The degree of water repellence decreases with increase in moisture content and temperature. Agricultural management strongly influences the hydrophobicity of SOM. Decline in soil organic C (SOC) pool by cultivation leads to decrease of hydrophobicity as well as of microbial activity and aggregate stability.^[3]

Several approaches using modern and effective analytical techniques are available for the characterization of SOM

and humic substances associated with bulk soils. These techniques involve the use of chemolytic methods, pyrolysis, thermochemolysis, compound specific-stable isotope, and radiation analysis. Besides these techniques, spectroscopic technique such as Fourier transform infrared (FTIR) spectroscopy is used for the analyses of SOM composition. The FTIR spectra of humic macromolecules contain a variety of bands that are diagnostic and could serve as a valuable tool to characterize the principal classes of chemical groups of which SOM is comprised. A synchrotron-based FTIR technique has been applied to determine composition of SOM extracted from the silt and clay fractions of soils.^[6] The FTIR technique is utilized to characterize SOM functional groups depending on land use and management practices. Based on FTIR analyses and evaluation of the intensities of oxygen-containing functional groups to the aliphatic and aromatic (referred to as recalcitrant) groups, the highest ratio is observed in the humic acids from the vetch/rye system with fertilizer N, compared with either rye alone or no cover crops.^[7] Isolation and extraction of humic substances are a time-consuming process, and extraction of SOM by various extraction agents is often incomplete due to the bonding with the mineral particles. Besides analyses of extracted humic substances, FTIR technique can therefore be directly used for the study of SOM composition in bulk soil samples. While using bulk soil samples, the FTIR spectra can be analyzed at absorption bands that indicate hydrophobic (CH-groups) and hydrophilic (CO-groups) functional groups. For hydrophobic methyl and methylene groups, the CH bands occur at 3020–2800 cm^{-1} ,^[3] and for hydrophilic amide and carboxylic acid or ketone groups, the C=O bands occur at 1740–1700 and 1640–1600 cm^{-1} . Focusing on analyzing of these ranges of spectra excludes any overlapping by absorption bands originating from other functional groups. Furthermore, hydrophobic/hydrophilic functional group ratio can be calculated in order to assess soil wettability and soil repellency.^[8] Based on FTIR spectroscopy, Capriel et al.^[3] defined a hydrophobicity index as the aliphatic C/total organic C ratio to characterize the degree of hydrophobicity of the SOM. Capriel and colleagues observed a close relationship between hydrophobicity of organic matter and soil texture. The organic matter of sandy soils contained more aliphatic C–H units than that in the clayey soils.

It has been demonstrated that management practices that increase SOC content may increase water repellency and decrease wettability. Urbanek et al.^[9] studied the spatial distribution of C and groupings of C–H and C=O compounds in three horizons in a silty loam Anthroisol, under long-term grassland pastures and also short-term conservation tillage wheat, and conventional tillage maize. They observed that total SOC content within individual aggregates and size classes varied considerably and were influenced by soil depths and management practices. More hydrophilic C=O groups were observed in maize and grassland biomes, where the plant biomass was greater than in

wheat. Total SOC content was strongly correlated with hydrophobic (C–H) groups, but not with hydrophilic groups. Similarly, a highly significant positive correlation was observed between SOC content and hydrophobic functional groups in soil samples taken from a long-term fallow experiment.

A good soil structure is important to sustaining long-term crop production on agricultural soils. One of the measures to form and maintain soil structure is the stability of soil aggregates in water, and this is influenced mostly by both the quality and the quantity of SOM pool. Several studies focused on the use of organic materials to improve soil structural stability have observed positive effects of total organic matter, whereas others have indicated that it is the humified fractions rather than the total amount per se that are responsible for aggregate stabilization. The practical implication of these observations is that soil amendment with organic materials containing substantial amounts of hydrophobic compounds can stabilize soil aggregates more than those with predominantly hydrophilic compounds.^[10]

CONCLUSION

There are many direct and indirect criteria for the assessment of the SOM quality. Most frequently, extraction and fractionation of humic substances mainly, humic acids and fulvic acids and calculation of so-called color quotient $Q_{4:6}$, are used. The main problems with these classical methods are difficulties with the interpretation of results and high demand of time and labor. Techniques involving determining the labile components of SOM are used for SOM quality evaluation.

Besides these techniques, non-destructive FTIR spectroscopy distinguishing hydrophobic and hydrophilic functional groups in SOM is rapid, and a less time-consuming method that may be useful for further analyzing SOM quality and improving interpretations of its physicochemical properties. It can also increase the knowledge of the effects of organic amendments on the turnover of SOM and to identify soil-amending practices based on the management of organic by-products.

Abstract

The most important effect of hydrophobicity is the controlling of soil water dynamics. Water repellency affects a wide range of physical, chemical, and biological properties and processes of soil and may have a significant effect on field capacity, solute transport in the unsaturated zone, soil water balance, aggregate stability, soil erosion, soil fertility, and the protection of soil organic matter against microbial degradation. A quantitative understanding of important mechanisms associated with hydrophobicity, e.g., the temporal dynamics of hydrophobicity and the spacial moisture pattern in soil, is needed.

INTRODUCTION

Many processes such as particle wetting, imbibition into porous media, adsorption, flocculation, or dispersion depend on interfacial interactions between soil solids and soil liquid. Hydrophobicity (“fear of water”) and hydrophilicity (“affinity to water”) are qualitative terms that describe the extent of interaction of surfaces with water. Hydrophobic surfaces generally repel water and tend not to absorb water, mix with it, or adsorb it. Hydrophilic surfaces show the opposite behavior.

Water repellency has been observed in sand, loam, clay, peat, and volcanic ash soils, all over the world. Research suggests that under certain conditions most soils display water repellency to some degree. Particularly sandy soils, with a comparatively smaller specific surface, are prone to hydrophobicity. Hydrophobicity, or water repellency, is caused by natural soil organic matter (SOM). SOM either covers the mineral grains as thin coatings or exists as particular organic matter, reducing potentially in both cases the wettability. The origin of SOM is mostly plant-derived like roots or plant tissues, plant-derived waxes or organic acids, fungal hyphae or microbial organic acids, and polysaccharides. For more information, see the entry *Water-Repellent Soils* (p. 2546).

HYDROPHOBICITY, WETTABILITY, AND CAPILLARITY

Interfacial interaction is mainly controlled by the interfacial tension, defined as the surface energy per unit area

(or sometimes as force per unit length) of the interface between two phases. Each phase by itself is characterized by its surface tension, which actually is the interfacial tension between this phase and a gas (the identity of which is unimportant because of its very low density). The interfacial tension can be estimated from the individual surface tensions by a variety of possible correlations.^[1] In soil, water with a high surface tension of about 72 mN/m (force per unit length) plays a dominant role. Surface tensions of soil may range from 20 to 60 mN/m.^[2] Surface tensions of solids range from 500 mN/m for metals and minerals (high-energy surfaces), depending on their hardness and melting point, down to 10 mN/m for organic surfaces.

Hydrophobicity/hydrophilicity of a surface can be quantitatively measured by the equilibrium contact angle (c.a.) that water makes with this surface in air. The c.a. is defined as the angle (°) formed between the tangent to the solid–air interface and the tangent to the liquid–air interface at the three-phase contact line, measured on the water side (Fig. 1). The c.a., θ , on ideal solid surfaces (i.e., smooth, rigid, chemically homogeneous, insoluble, and non-reactive) is related to the interfacial tensions by the Young equation,^[3] which can be given as

$$\sigma_{LV}\cos\theta = \sigma_{SV} - \sigma_{SL} \quad (1)$$

where σ_{SV} is the surface tension of the solid–gas interface, σ_{LV} the surface tension of the liquid–gas interface, and σ_{SL} the solid–liquid interfacial tension. This c.a. is

Fig. 1 Schematic representation of the various degrees of hydrophobicity as well as the corresponding solid surface tension and the reduced spreading coefficient.

referred to as the ideal or Young c.a. Although c.a. values may vary continuously depending on the surface tension of the solid in question, it is convenient to think in terms of three different wetting situations (Fig. 1): Complete wetting, for which the ideal c.a. is zero and the liquid forms a very thin film, partial wetting with $0^\circ < \theta \leq 90^\circ$, and partial wetting with $\theta > 90^\circ$, which is sometimes referred to as non-wetting. Wetting systems can also be characterized by the spreading coefficient, S (mN/m), defined by

$$S = \sigma_{SV} - (\sigma_{SL} + \sigma_{LV}) = \sigma_{LV}(\cos \theta - 1) \quad (2)$$

This is a measure of the energy per unit area needed to replace a solid–air interface by a solid–liquid or liquid–air interface ($S \geq 0$ for complete wetting and < 0 for partial wetting).

The c.a. that a liquid forms with a solid surface controls not only the spreading of the liquid on the surface but also its imbibition into a porous medium.^[4] When a liquid is brought into contact with an unsaturated porous medium like soil, it attempts to form the appropriate equilibrium c.a. with the inside surface of the soil pores. This is associated, in many situations, with the formation of a curved liquid–air interface. This curvature, in turn, implies a pressure difference across the liquid–air interface, which is given by the Young–Laplace equation.^[3] In a cylindrical, straight capillary, this pressure difference, ψ (Pa), is given by

$$\psi = p^g - p^l = 2\sigma_{LV} \frac{\cos \theta}{r} \quad (3)$$

where p^g (Pa) is the pressure in the gas phase, p^l (Pa) the pressure in the liquid, and r (m) the radius of the capillary. If this pressure difference is positive (i.e., $\theta < 90^\circ$), the liquid spontaneously penetrates into the porous medium. Hydrophobic surfaces ($\theta > 90^\circ$) feature capillary depression, unless the liquid comes in the form of small droplets. In the latter case, infiltration into porous material is possible even for a c.a. $> 90^\circ$.^[5]

ASSESSMENT OF HYDROPHOBICITY

Numerous effects such as surface roughness, chemical heterogeneity, wetting dynamics, particle shape, and gas adsorption give rise to c.a. hysteresis, i.e., larger c.a.s for an advancing wetting front and smaller c.a.s for a receding wetting front, as compared with the intrinsic equilibrium c.a.^[6–9] The stochastic combination of heterogeneous surface properties and pore topologies encountered in natural porous media emphasizes that observations relate, at best, to the apparent c.a., which does not directly represent the ideal c.a. at interfaces within the medium.^[10]

For soil, indirect assessment methods have to be applied.^[11] The most frequently applied methods include the water drop penetration time test (WDPTT) and the molar ethanol droplet test (MEDT). In MEDT, the molarity of water and ethanol mixtures is varied repeatedly, until droplets of the mixture infiltrate into the soil in a pregiven length of time. Roy and McGill^[12] suggested a standardized procedure for MEDT to improve its reproducibility. Data obtained, e.g., with WDPTT indicate that water repellency is time dependent. To measure the initial c.a. of a dry powder, Siebold et al.^[13] applied the capillary rise method for wettable or slightly repellent mineral particles. Later, Bachmann et al.^[2] proposed the Wilhelmy plate method, which allows the measurement of dynamic advancing and receding c.a. for wettable and repellent soil particles.

EFFECTS OF HYDROPHOBICITY

Reduced wettability covers a wide range of severity and is often too weak to be detected by visual diagnosis. This usually less extreme manifestation of water repellency is often referred to as subcritical repellency.^[14] Extreme soil water repellency can lead to a complete loss of infiltration capacity, enhancing runoff from hillslopes, which, in turn, may enhance soil erosion and

cause the occurrence of landslides. Enhanced ponding at the soil surface favors preferential flow in the soil.^[15] Such soil wetting patterns either force soil water into macropores or lead to persistent non-uniform soil wetting patterns, which implicate a rapid transfer of solutes into the groundwater.^[16] Compared with uniformly wetted surfaces, a surface having a pattern of dry ridges and wet furrows can potentially reduce the average evaporation rate of a field. The effect of water repellency is not restricted to dry soil. An increase of water repellency with increasing soil water content was phenomenologically observed also for moist soils.^[17] Simultaneously, a decrease of hydrophobicity with time was observed. So far, the prediction of the critical water content, at which the transition from hydrophilic to hydrophobic behavior of soil particle surfaces occurs, can be rated as an unsolved problem.

For wetting soils, Morrow^[18] presented a relation between the retention of a liquid in a porous medium and the intrinsic c.a. θ_E measured on a plane and clean surface, where θ_E is considered as a thermodynamic sound property that defines the system wettability under equilibrium conditions (Fig. 2).

A comparison of the c.a. measured on plane plates with those either assessed in roughened capillaries (advancing c.a. θ_A and receding c.a. θ_R) or derived from retention data (Φ_A and Φ_R) suggests that these operative c.a.s were

in reasonable agreement with intrinsic c.a. θ_E . So far, only few data exist for real soils to quantify the effect of the degree and the persistence of hydrophobicity on water retention.

Hydrophobicity, however, not only has negative effects. For example, hydrophobic surface layers have been used for water harvesting and for preventing evaporation of soil water in arid climates.^[15] With respect to carbon sequestration in soil, it was shown that the higher the degree of hydrophobicity of the humic material, the larger is the stabilization, i.e., protection against microbial degradation, of organic carbon because of the increased aggregate stability.^[19]

CONCLUSION

Hydrophobicity of natural soils is mainly caused by SOM of natural origin. It is becoming increasingly evident that, besides strong hydrophobicity ($\theta > 90^\circ$), subcritical repellency ($0^\circ < \theta \leq 90^\circ$) seems for many soils more the rule than the exception. Methods allow only the assessment of hydrophobicity on a small sample scale. On the field scale, it is difficult to separate experimentally the influence of hydrophobicity on the soil's hydraulic properties from that of other factors such as the pore topology and its connectivity. However, a quantitative understanding of the

Fig. 2 Equilibrium c.a. θ_E vs. c.a. in capillaries (advancing angle θ_A and receding angle θ_R) and c.a. Φ determined from porous media for drainage Φ_R and imbibition Φ_A (the saturation of the porous medium is indicated by WC).

Source: Data from Morrow.^[18]

hydrophobic behavior of soils in time and space is a prerequisite to increase the knowledge on fundamental physical, chemical, and biological processes in terrestrial ecosystems.

Abstract

Inceptisols are important soils worldwide, covering about 14.5% of the earth's ice-free surface, with the amount expected to increase as ice and frozen soil melts. *Inceptisols* are important farmlands on level areas in semiarid climates, infloodplains, and on terraced hillslopes. Inceptisols are considered an intermediate stage of development between *Entisols* and the more highly developed soil orders preceding them in the *Key to Soil Orders*, except where sandy parent material, very steep slopes, or wet, dry, or cold climate permanently limit their development. Modal *Inceptisols* have pale or thin surface horizons (*ochric epipedon*) and a minimally developed subsoil (*cambic horizon*). *Inceptisols* can form in any type of parent material except thick organic deposits, in any *soil moisture regime* other than *aridic* or *torric* (where they would be identified as *Aridisols*), and in any *soil temperature regime*. They are concentrated in four major settings—cold regions, dry regions (*ustic* and *xeric*), wetlands, and young geological surfaces (such as recent or very steep parent material deposits).

INTRODUCTION

Inceptisols

Inceptisols (terms from Soil Taxonomy^[1,2] are italicized.) are a unique soil order. They are essentially intermediate in expressed development between soil orders that precede them in *Key to Soil Orders* and soils that have no diagnostic horizons other than *anthropic*, *ochric*, or *albic* (*Entisols*). *Inceptisols* are mineral soils that have significant surface or subsoil alteration, being morphologically similar to some *Gelisols*, *Andisols*, *Spodosols*, *Vertisols*, and *Entisols*. Similar soils in *aridic* or *torric soil moisture regimes* that have *cambic* horizons classify as *Aridisols*. Their development has been or is limited by one or more of the five soil-forming factors (parent material, climate, relief, organisms, and time). For example, soils developing on steep mountain slopes from acid sedimentary rocks have limited surface (*ochric epipedon*) and subsoil horizon development (*cambic* or *fragipan* diagnostic horizon) because of steep slope and acidic parent material. If they have more than 8% clay, they must have dewatered enough following aqueous deposition to be able to support the weight of humans and most livestock (have a *n* value of more than 0.7) to avoid being *Entisols*. Note that there are also almost 300 soil series in the United States that have the morphology of *Inceptisols* but have sandy subsoils that are not allowed for a *cambic*

horizon, and are therefore considered *Entisols* because of the absence of a diagnostic subsoil horizon and limited potential for further development. *Inceptisols* can form in any type of parent material except thick organic deposits on any slope or landform from floodplains to mountaintops and are found under all vegetation types. They may occur in any *soil moisture regime* other than *aridic* or *torric* and any *soil temperature regime*. Inceptisols range in age from recent to very old, dependent mainly on the parent material and climate. Older deposits must be limited from developing by the amount of quartz sand, the climate, or the slope.

OCCURRENCE

Inceptisols are concentrated in four major settings—cold regions, dry regions (*ustic* and *xeric*), wetlands, and geologically young surfaces (such as floodplains, volcanic and glacial deposits, and steep or highly erosive slopes). The area of *Inceptisols* is expected to increase in cold regions such as Siberia, Canada, and Alaska where *permafrost* is melting. About one-fourth of the land area of Europe and Central America and less than one-tenth of the other continents consist of *Inceptisols*. Approximate areas of each suborder^[3] by continent are listed in Table 1. *Inceptisols* make up about one-quarter of the soils in Europe and

Table 1. Area (km²) of *Inceptisols* on different continents.

SUBORDER	North America	Central America	South America	Europe	Africa	Asia	Australia/Oceania	Global
<i>Aquepts</i>	348,880	45,966	413,983	194,742	369,402	1,394,880	2,878	2,770,731

Central America. Altogether, *Inceptisols* occur on about 14.5% of the ice-free land surface of the earth. *Inceptisol* distribution is shown in Fig. 1.

CORRELATION

The major categories (suborders) of *Inceptisols* are *Aquepts* (aquic conditions), *Gelepts* (frozen), *Cryepts* (cold, short growing season), *Ustepts* (alternating moist and dry with moist summers or no defined winter season), *Xerepts* (alternating moist and dry with dry summers and moist winters), and *Udepts* (moist in all seasons). Table 2 correlates Soil Taxonomy suborders^[1,2] with World Reference Base reference groups.^[4]

Suborders have been established because of major differences in climatic factors that affect soil genesis.

AQUEPTS

The *Aquepts* are the suborder of *Inceptisols* that formed with near-surface redoximorphic features (*aquic conditions*) under extended saturated conditions during biologically active seasons. Some have a histic epipedon and some have accumulated iron sulfate or sodium in the upper 50 cm. *Aquepts* occur in low-lying coastal areas, glacial lake plains, floodplains, playas, and in other nearly level areas where shallow groundwater or perched water exists. Major areas are sub-Arctic areas, humid areas that

were covered with the most recent glaciation, wet floodplains and lake plains such as eastern Angola and western Venezuela, irrigated paddies of Eastern China, and wet, floodplains and flooded terraces of major rivers including the Mississippi and Ganges–Brahmaputra.^[1]

GELEPTS

The *Gelepts* are the *Inceptisols* that have a mean annual soil temperature at or below 0°C at 50 cm depth (*gelic soil temperature regime*). They occur on any slope and landform. *Gelepts* also either do not have *permafrost* within 100 cm or do not have both *permafrost* within 200 cm and evidence of cryoturbation (*gelic materials*) within 100 cm. They occur where *permafrost* has thawed or where relief and cold temperatures prevent advanced soil development. These soils are found in central Alaska to west central Canada, east central Canada, in high elevations of Scandinavia, in central, eastern, and southeastern Siberia, northern Mongolia, and in Patagonia.^[1]

CRYEPTS

Cryepts are the *Inceptisols* with persistently cold climates' mean annual soil temperature between 0°C and 8°C at 50 cm depth (*cryic soil temperature regime*), but they do not have *permafrost* within 1 m. They occur on any landform in northern latitudes and in high mountains around the globe where soil development is limited by temperature, parent material or relief, and the soil temperature regimes are *cryic* but not as cold as *gelic*.^[1]

USTEPTS

The *Ustepts* are the suborder of *Inceptisols* that receive most of their precipitation in the summer when

evapotranspiration is highest or they do not have a defined winter (*ustic soil moisture regime*). Native vegetation is typically grassland, shrubland, or savanna. They occur on any freely drained landform and that are not persistently cold. Major areas of *Ustepts* occur on major river floodplains, terraces, glacial till plains, hills, and foothills.^[1] *Ustepts* form where precipitation is sufficient to cause weathering and leaching but is insufficient to completely leach the by-products. The effectiveness of the precipitation is severely limited by either slope or high evapotranspiration or both. Cemented layers or bedrock prevents deep leaching in some of these soils. They occur largely in Central America, parts of the Andes, Europe, East Africa, and India.

XEREPTS

The *Xerepts* are the suborder of *Inceptisols* that are moist in the winter and dry in the summer (*xeric soil moisture regime*). They receive most of their precipitation in the winter season when evapotranspiration is lowest, but experience a summer moisture deficit in most years when evapotranspiration is highest (Mediterranean climate). Native vegetation ranges from grassland or chaparral to forest. They occur on any freely drained landform if the temperature is not persistently cold or hot. Major areas of *Xerepts* occur in mid-latitude coastal areas and nearby zones with Mediterranean climate.^[1] *Xerepts* occur in areas where precipitation is sufficient to cause weathering and leaching, but is insufficient to completely leach the by-products in some areas. The effectiveness of the precipitation is enhanced by low evapotranspiration rates in winter. These soils are dry in summer when evapotranspiration rates are highest. They occur largely in northwest America and Africa and Southern Europe to Turkey.

UDEPTS

The *Udepts* are the suborder of *Inceptisols* that do not experience more than short periods of moisture deficit in the growing season for many years (*udic soil moisture regime*). The moisture is distributed evenly enough to keep up with evapotranspiration losses most of the time. Native vegetation is typically forest. *Udepts* occur on freely drained landforms in climates where the temperature is not persistently cold. Fig. 2 shows an acidic *Udept* from the humid mountains of the Eastern United States. *Udepts* occur in areas where precipitation is sufficient to cause abundant weathering and leaching, unless steep slopes decrease the effectiveness of the moisture or some cemented or dense subsurface horizon or feature restricts deep leaching of the weathering by-products. They occur in humid area floodplains and in steep areas in humid hills and mountains in the Eastern

Fig. 2 An *Inceptisol* profile as shown on the poster of the 12 soil orders of Soil Taxonomy.

Source: From Soil Survey Staff.^[5]

and Northeastern United States, Central Europe, Andes, Himalayas, Southeastern Asia, and the islands of New Guinea and New Zealand.^[1]

SOIL GENESIS

Organic matter accumulates in the surface if the water tables stay very near the surface round the year, and mineralization of organic matter is restricted, forming organic or humus-rich mineral surfaces (*histic*, *mollic*, or *umbric epipedons*). Some cool, high-elevation *Inceptisols* have thick surface deposits of organic litter that is not saturated (*folistic epipedon*). Some *Inceptisols* in marine estuaries or dry climates have accumulated sodium and other soluble salts in the surface (*salic horizon*) through upward movement of an element-rich or saline water table. Evapotranspiration removes water but leaves precipitated salts behind as the water table recedes. In dry climates, incomplete leaching leaves subsoil water enriched in soluble

compounds that precipitate and cement the soil fabric with silica (*duripans*), gypsum (*gypsic* or *petrogypsic horizons*), or lime (*calcic* or *petrocalcic horizons*). Sandy parent materials may accumulate a significant number of very thin bands (*lamellae*) of layered clay in the subsoil where the soil water resides and dries. In cool and humid areas, compounds with organic carbon and either aluminum or iron may accumulate in the acidic subsoil (*spodic materials*), and thin (<10 cm) *spodic* horizons may occur. *Cambic horizons* form from incomplete accumulation of these materials in textures finer than very fine sands and loamy very fine sands.

Inceptisols with *aquic conditions* are saturated in the upper soil for more than a few consecutive days during seasons of biological activity. Water fills all the pores in a horizon when rainfall exceeds evapotranspiration, and either some subsoil horizon or layer restricts downward movement, groundwater rises in the soil, or porewater moves very slowly through a horizon. In tidal marshes or areas where reduced parent materials high in sulfides (*sulfidic materials*) are exposed to oxygen by mining or artificial drainage, a *sulfuric horizon* quickly forms and pH drops to very low levels. Water- and root-restricting subsoil horizons form in moist climates when restricted leaching leaves subsoil water enriched in soluble iron compounds that precipitate and cement the soil fabric to form continuous *plinthite* or *petroferrie (ironstone) horizons*. In moist climates, non-cemented, root-restricting subsoils (*fragipans*) may form through internal desiccation or compaction or partial cementation. The persistently cold (*cryic*) soils in northern latitudes or high elevations have a slower rate of soil-forming processes than do warmer soils. On gentle slopes, volume changes from alternating freezing and thawing may cause churning (*cryoturbation*). *Cryic* soils on steep slopes have shallow profiles because of reduced effectiveness of precipitation, increased runoff, and accelerated losses from erosion and mass movement. Volcanic materials ejected into the air, and some other physically and chemically similar materials may weather to form amorphous clays instead of layered clays. Soils rich in amorphous clays have *andic soil properties* such as high surface area, high retention of charged elements and compounds, high water-holding capacity, and very low bulk density. Deep, wide cracks and large volume changes occur in soils that wet and dry often and contain a high amount of layered clay that has high shrink-swell potential. *Inceptisols* form on major floodplains and low terraces that rarely flood or are very young deposits. Some of these soils still contain evidence of sediment deposition from flooding in the subsoil that has not been completely destroyed by soil-forming processes. *Cambic horizons* form from incomplete action of the alteration processes mentioned before.

Extremely old, highly weathered and continuously leached *Inceptisols* have *cambic horizons* that are dominated by low chemical and physical activity clays and

oxides. *Cambic horizons* may also form from removal of gypsum and lime by percolating soil water over time. Often the leached horizon develops soil structure and becomes lighter or brighter in color or accumulates red colors from the release of oxidized iron compounds. *Inceptisols* have formed on some shoulder positions from more developed soils in intensively farmed areas that have had long-term accelerated erosion. These soils may have had diagnostic horizons removed by accelerated erosion because of farming practices and their convex landscape position.

USE AND MANAGEMENT

Gently sloping, deep *Inceptisols* are well suited to use as cropland. Moderately sloping areas that are not terraced are better suited for biofuels, forages, grazing, forest products, or agroforestry because of the erosion hazards. Areas that are very steep or shallow can be used for forest products, rangeland, wildlife habitat, or recreational uses.

Udepts used for cropping or pasture seldom need irrigation to supplement growing season soil moisture. Native areas are used for forest products, recreation, and wildlife habitat. However, irrigation is often needed to grow annual crops on *Ustepts*. Without irrigation, moisture conservation farming practices and terracing are needed for growing forages and drought-tolerant crops. Perennial crops such as biofuels, root crops, and trees are better able to take advantage of stored moisture. *Xerepts* are important soils for growing small grains and other winter annual crops. Summer crops such as grapes, peas, lentils, and mustards are able to use soil moisture stored during the previous winter season. Native areas are used for timber production, grazing, and wildlife habitat. *Ustepts* and *Xerepts* with a shallow cemented root-limiting layer can be mechanically ripped to allow deeper moisture percolation and increase the rooting zone. Note that if the cemented layer is mechanically ripped for agriculture, these soils become *Entisols*. However, ripping is not financially practical unless irrigated specialty crops can be grown.

Acidic *Inceptisols* with low quantity of nutrients (low base saturation) are separated from high base saturation soils in all but the *Aquepts* suborder. These soils occur on uplands and on minor floodplains that drain mostly acidic rocks and soils. They may be used to grow native crops but must be limed to raise the pH to grow most introduced crops, especially where free aluminum is present in the soil solution and aluminum toxicity may occur. These acidic soils are inherently infertile and must be fertilized to sustain crops or forages, provided the soil mineralogy has sufficient capacity to adsorb the added nutrients. Agroforestry and perennial biofuel cropping may be used in combination with organic

fertilizers and lime on some of these soils. Extremely weathered and leached rainforest soils have most of their nutrients tied up in the above- and belowground organic matter and cannot sustain continuous cropping without the addition of fertilizer and other soil amendments.

Inceptisols on major floodplains typically have high quantity of nutrients (high base saturation). These soils are some of the most important cropland soils in the world. They may be used to grow almost any type of vegetation, depending on their texture, climate, and available moisture.

Aquepts and *Udepts* with *sulfuric horizons* have extremely low pH and are not suitable for agriculture. They can be remediated only if the remaining sulfide-bearing materials are prevented from oxidizing, either by plugging drainage ditches or by deeply burying the layer with better soil. *Aquepts* in warm climates have value for raising rice or water-tolerant specialty crops. Those that have been drained can be used for many types of forages, agricultural crops, biofuels, or forest products (timber or pulpwood). Saline and sodic *Inceptisols* must be drained to prevent the saline water table from rising near the surface if they are used for growing crops. Rainfall or non-saline irrigation water can then leach the excess sodium and salts from the surface. These soils are then suitable for growing a wide variety of crops, depending on their climate and texture.

Cryepts are not suited to many crops but may be used for small grains, berries, potatoes, forest products, wildlife habitat, and recreation. The *Cryepts* that are in high latitudes are more suited to cropland because of the long day-lengths than those at high elevations. The *Cryepts* that occur at high elevations are important sources of streams and fresh water aquifers because they typically have high runoff from rain and melting snowfall and decrease evapotranspiration.

Plaggen surfaces have many uses for agriculture because they are fertile and have high organic carbon and water-holding capacity in the surface. *Anthropic* surfaces are chemically suitable for agricultural fields or gardens but may need irrigation. Soils with high accumulation of organic carbon in the surface have better structure and higher water nutrient-holding capacity than other surface soils lower in carbon. Natural fertility is variable.

CONCLUSION

Inceptisols share similarities to all other soil orders. Soil development of *Inceptisols* has been or is limited by one or more of the five soil-forming factors (parent material, climate, relief, organisms, and time). They are mineral soils more developed than *Entisols*, can support the weight of humans and most livestock, and have diagnostic surface or subsurface horizons that are not too sandy to have continued development potential. However, *Inceptisols* either do not have the diagnostic horizons, materials,

permafrost, or other features of the more developed soil orders that precede them in *The Keys to Soil Taxonomy*. *Inceptisols* can form in any type of parent material except thick organic deposits. *Inceptisols* may occur in any *soil moisture regime* other than *aridic* or *torric* and in any *soil temperature regime*. *Inceptisols* are concentrated in four major settings—cold regions, dry regions (*ustic* and *xeric*), wetlands, and young geological surfaces (such as floodplains, volcanic and glacial deposits, and steep or highly erosive slopes). The area of *Inceptisols* is expected to increase in cold regions where *permafrost* is melting. *Inceptisols* are common in Europe and Central America. The major categories (suborders) of *Inceptisols* are *Aquepts* (aquic conditions), *Gelepts* (frozen), *Cryepts* (cold), *Ustepts* (alternating moist and dry with moist summers or no defined winter season), *Xerepts* (alternating moist and dry with dry summers and moist winters), and *Udepts* (moist in all seasons). They are considered important farming soils in level areas and highly terraced hillslopes.

National Bureau of Soil Survey and Land Use Planning, Indian Council of Agricultural Research (ICAR), Nagpur, India

Abstract

Soils of India have been categorized into eight groups as per traditional system. A project undertaken by ICAR-NBSS&LUP on Soil Resource Mapping (SRM) of the country adopted the physiographic heterogeneity as the basis for identifying nature of soils, their constraints, potentials, and broad order level classification. The project reported the occurrence of seven soil orders which are discussed with respect to their characteristics, constraints, potentials, and land use aspects.

INTRODUCTION

Precise knowledge of nature of soils (limitations and potentialities) and their spatial distribution is one of the most important prerequisites for proper land use planning that could ensure sustainable agricultural production.

The Indian Council of Agricultural Research (ICAR) in 1953 categorized Indian soils into the following eight major groups, namely: 1) alluvial soils; 2) black soils; 3) red soils; 4) laterite and lateritic soils; 5) forest and mountain soils; 6) arid and desert soils; 7) saline and alkaline soils; and 8) peaty and marshy soils. This has been a traditional system of classification of Indian soils widely followed in India.

The Soil Resource Mapping (SRM) project of the country undertaken by the ICAR-National Bureau of Soil Survey and Land Use Planning on 1:1 million scale (during the period 1986–1996) was based on the identification of relationship between landform (physiography) and soil.^[1]

SOIL–PHYSIOGRAPHY RELATIONSHIP

Soils of the identified physiographic units are discussed below with respect to their constraints and potentialities.

Hill Ranges (Ghats)

In hill ranges, 24.1% is moderately to very steeply sloping; 16.2% soils of the hill ghats are shallow to extremely shallow as against 48.6% deep to very deep soils; 62.6% soils are moderately well drained to well drained, and

24.8% are somewhat excessively drained to excessively drained; 43.5% soils are clayey, whereas 22% are loamy; 77.7% soils are severely to very severely eroded; 16.9% soils are affected by slight sodicity. The major soil orders are Inceptisols, Mollisols, and Ultisols.

Central Uplands

In central uplands 4.5% soils are moderately steep to very steeply sloping; 15.1% soils are shallow to extremely shallow as against 61.9% deep to very deep soils; 83.0% soils are moderately well drained to well drained, and 10.8% soils are somewhat excessively drained to excessively drained; 47.6% soils are clayey, whereas 35.4% are loamy and 2.4% are sandy; 79.4% area is severely to very severely eroded; 5.5% soils are moderately to moderately strongly saline; 74.1% soils are slightly sodic, whereas 1.1% soils are affected by strong to very severe sodicity. Inceptisols, Vertisols, and Entisols are the major soils (in this order). Workability and drainage are the main challenges in managing Vertisols.

Indo-Gangetic Plains (IGP)

In IGP, 99.2% soils of the IGP are deep to very deep soils; 67.5% soils are well drained to moderately well drained, and 28.6% soils are imperfectly to very poorly drained; 76.5% soils are loamy, whereas 14.1% are clayey; 12.3% soils are severely to very severely eroded; 14.6% soils are moderate to moderately strong in salinity; 10.2% soils are affected by moderate sodicity, and 11.8% are very severe to

strongly sodic. Dominant soils are Inceptisols, Alfisols, and Entisols. Soils under arid and semiarid parts of the IGP lack organic carbon due to high rate of decomposition. Imbalanced use of fertilizer is one of the major problems in this region. Deficiencies of nutrients occur in different combinations such as phosphorus (P) and zinc (Zn); and nitrogen and P. Introduction of irrigation without the provision of drainage led to soil salinization and alkalization within a few years in this region due to rise in the groundwater table containing high proportion of sodium. Relic salinity (legacy of the Tethys Ocean) and intensive irrigation in semiarid climate have combined to cause salinity. Excessive tillage and wet tillage (puddling), use of rotavators, and freewheeling of tractors and harvesters (combined) in the IGP have, in general, resulted in gradual compaction of soils, leading to a reduction in long-term soil productivity, especially under rice–wheat cropping system. However, subregion-specific strategies of soil management could arrest the stagnation of yields that are being reported widely. Balanced use of fertilizers alone could achieve significant increase in yield, especially in eastern IGP where fertilizer usage is very low.

The fact that the fertilizer was the key input in augmenting food grain production (after the availability of the seeds of high-yielding crop varieties) is evident from the increase in fertilizer ($N_2 + P_2O_5 + K_2O$) consumption from 1.98 Mt in 1969–1970 to 18.07 Mt by 1999–2000. Nevertheless, the average annual increase in fertilizer consumption witnessed a declining trend in the following three decades, as reflected by 16.5% during 1970s, 12.04% during 1980s, and only 5.6% during 1990s.^[2] A simple regression analysis between the food grain production and fertilizer consumption between 1960–1961 and 1999–2000 showed that the partial factor productivity of fertilizers has been continuously declining.^[2] The data available from some centers under the Indian Institute of Farming Systems Research, Modipuram, also indicate a reduction in crop response to fertilizer applications, especially when balanced fertilization is not practiced.

About 67.1% soils are moderately well drained to well drained, whereas 27.4% soils are imperfectly to poorly drained; 55.1% soils are clayey; 49.9% soils are severely eroded, whereas 48.3% are moderately eroded, 4.2% soils are moderately to strongly saline, and 2.9% soils have moderate to moderately strong salinity; 17.8% soils are slightly sodic. Dominant soils are Inceptisols and Alfisols. Acid sulfate and potential acid sulfate soils are reported to occur in the Sunderbans, 24 Parganas (South), West Bengal, and Kuttanad, the Rice Bowl of Kerala, which adversely affect crop yield.^[3,4] These soils develop as a result of the drainage of parent materials that are rich in pyrite (FeS_2). The acid sulfate soils have the problems of extreme acidity ($pH < 4.0$) and have toxic quantities of iron (Fe), aluminum (Al), and sulfur (S) which usually limit the crop choice and productivity. Potential acid sulfate soils are poorly drained soils with a high content of FeS_2 . The pH of the soils would

be neutral or slightly acidic in the field. Upon drainage, the soil becomes strongly acidic, which directly affects the growth of plants as a result of Al and Fe toxicity and indirectly decreases the availability of phosphorus and other nutrients. The other constraints are poor contents of major nutrients, low base status, and hydrogen sulfide toxicity.

The Islands

In islands, 31.3% soils are very steeply sloping; 6.9% soils of the islands are shallow to extremely shallow as against 80.9% moderately shallow to moderately deep soils and 12.1% deep to very deep soils; 67.8% soils are moderately well drained to well drained, and 24.4% are somewhat excessively drained to excessively drained; 89.8% soils are loamy, whereas 6.2% are sandy; 84.6% soils are severely to very severely eroded, whereas 15.4% soils are affected by moderate erosion; 3.8% areas are strongly saline. Dominant soils are Inceptisols and Entisols. Mollisols also have significant presence in the islands.

Himalayan Mountains and Siwaliks

In Himalayan mountains and Siwaliks, 37.9% area is steeply to moderately steep sloping, and 14.4% area is moderately to gently sloping; 12.2% soils of the Himalayan region are shallow to extremely shallow as against 22.7% deep to very deep soils; 31.5% soils are excessively to somewhat excessively drained, and 21.8% soils are well drained to moderately well drained; 25.7% soils are loamy, whereas 6.5% are sandy; 50.2% area is severe to very strongly severe, and 3.1% area is moderately eroded; 9.7% soils are slightly sodic.

Northeastern Hill Ranges and Valleys

In northeastern hill ranges and valleys, 12.3% soils of the northeastern region are moderately deep against 86.6% deep to very deep soils; 46% soils are moderately well drained to well drained, and 36% soils are somewhat excessively drained to excessively drained; 57% soils are loamy, whereas 32.8% soils are clayey; 32.2% soils are moderately steep to very steeply sloping; 73.9% soils are affected by severe to very severe erosion, whereas 20.5% soils are moderately eroded. Only 0.7% soils are moderate to moderately strong in salinity, and 0.7% soils are strongly to very strongly sodic. Dominant soils are Ultisols, Alfisols, and Inceptisols. The northeastern hill region represents 55% of acid soils in India, despite contributing only 8% of the total geographic area. Toxicity of Al, deficiency of bases [e.g., calcium, magnesium, and potassium (K)], and low availability of phosphorous are the other major problems faced in managing these soils.

Western Plains

The region is dominantly covered with high and low dunes; 23.9% soils of the Western Plains are moderately shallow to moderately deep as against 71.3% deep to very deep soils; 57.8% soils are somewhat excessively drained to excessively drained; 57% soils are sandy, whereas 39.7% are loamy; 97.6% soils are strongly to very strongly saline, 8.8% soils are moderately to moderately strongly saline, whereas 4.8% soils are affected by sodicity. Dominant soils are Aridisols and Entisols.

Deccan Plateau

In Deccan Plateau, 29.1% soils are shallow to extremely shallow as against 62.3% deep to very deep soils; 17.5% soils are somewhat excessively drained to excessively drained; 53.3% soils are clayey, whereas 28.9% soils are loamy; 84.3% soils are severely to very severely eroded, whereas 9.9% soils are affected by moderate erosion; 3.7% soils are affected by moderate to moderately strong salinity; 1.5% soils are moderately sodic. Dominant soils are Inceptisols, Vertisols, and Entisols.

Eastern Plateau

In Eastern Plateau, 66.6% area is gently to moderately sloping, whereas 28.3% is level to very gently sloping; 21.6% soils of the Eastern Plateau are moderately shallow to moderately deep, and 21.4% soils are shallow to extremely shallow as against 56.9% deep to very deep soils; 70.8% soils are moderately well drained to well drained, 15.4% soils are somewhat

excessively drained to excessively drained, and 13.8% soils are very poorly to imperfectly drained; 59% soils are loamy, whereas 33.3% are clayey; 85.7% soils are severely to very severely eroded, whereas 14.3% are moderately eroded soils; 56.6% soils are slightly to moderately sodic. Alfisols, Inceptisols, and Entisols are the dominant soils; 85.7% soils are affected by severe to very severe erosion, whereas 14.3% are moderately eroded; 56.6% soils are affected by slight salinity, whereas 56.6% soils are affected by slight to moderate sodicity. Alfisols, Inceptisols, and Entisols are the dominant soils.

Gujarat Plain

In Gujarat Plain, 28.6% area is gently to moderately sloping; 20.3% soils of Gujarat Plain are shallow to extremely shallow as against 47.5% deep to very deep soils. 81.3% soils are moderately well drained to well drained, and 10% are somewhat excessively drained to excessively drained; 51.8% soils are clayey, whereas 41.8% soils are loamy; 61.5% soils are affected by severe to very severe erosion, whereas 32.7% soils are moderately eroded; 15% soils are affected by strong to very severe salinity problem, whereas 24.8% are moderate to moderately strong in salinity; 19% soils are moderately sodic, whereas 8.3% soils are strong to very strongly sodic. Dominant soils are Inceptisols, Aridisols, and Vertisols.

The physiographic unit-wise soil classification reported the occurrence of seven soil orders, namely, Inceptisols, Entisols, Alfisols, Vertisols, Aridisols, Mollisols, and Ultisols as discussed above. Area (%) of soils under different soil orders is given in Fig. 1, their geographical distribution in the country is presented in Table 1 (across the federal

states), and Fig. 2 presents the spatial distribution of soil orders in the country. We also describe soil order-wise characteristics, problems, and potentials to have a better insight into nature of soils of India.

Inceptisols

Vertic intergrades in Madhya Pradesh (MP), Gujarat, and Andhra Pradesh (AP) support crops like soybean, cotton, and groundnut. Paddy–wheat system is dominant in loamy textured soils in Uttar Pradesh (UP) and other IGP regions of the country. More than 42% of the area under these soils

is degraded due to water erosion. Management of these soils is critical to the food safety of India because agricultural production from these soils in UP and other IGP regions has served as food granary to the nation since the Green Revolution. Higher yields could be achieved on loamy and fertile soils with the use of high-yielding varieties, higher irrigation, fertilizers, and improved soil management practices apart from socioeconomic and external factors. These are the best agricultural soils and are used for growing most agricultural crops, especially wheat, rice, maize, groundnut, and berseem. Because of the injudicious use of irrigation water, some such soils have

Fig. 2 Spatial distribution of various soil orders in soils of India.

been rendered waterlogged and pose problems of soil salinity and/or sodicity mainly in Punjab, Haryana, and UP and thereby limit choice of crops.

The yields of crops have stagnated due to high degree of physical and chemical degradation of land, nutrient deficiencies and imbalances, depleting groundwater level, and pollution of soil and groundwater by nitrogen, phosphorus, and heavy metals.^[6] Buildup of salinity and/or sodicity, increased bulk density due to continuous puddling (rice crop), and excessive groundwater extraction are the major problems. In the semiarid tropics, erosion of shallow soils on the one hand and impeded drainage on the other are constraints of crop production.

Acidity is another major problem in Inceptisols occurring in all the states of the country except in Haryana, Punjab, Rajasthan, Gujarat, and Delhi. In general, soils are deficient in nitrogen, phosphorus, and humus but are well supplied with K and require judicious application of manures and fertilizers for sustainable farming. As a result of intensive cultivation, these soils exhibit second-generation problems, viz. nutrient deficiencies of S and Zn, receding and rise of groundwater table (as in central Punjab), and causing salinization in other areas adjoining Punjab and Haryana states. Inceptisols developed on coastal alluvium are found along seacoast of Karnataka, Kerala, Tamil Nadu,

AP, Odisha, West Bengal, and Goa. Stretches of coastal sands or sandy soils occur prominently in the coastal areas of Thanjavur district of Tamil Nadu, Bapatla in Guntur district of AP, and Puri district in Odisha where salinity and waterable do not pose problems and the sandy patches are put under plantations of coconut, cashew, and casuarinas.^[7]

Peaty soils (subgroup) occur in humid regions, have accumulation of high organic matter, and contain considerable amount of soluble salts. These soils are generally blue due to the presence of ferrous iron under anaerobic conditions and contain varying amounts of organic matter. Marshy soils of this type occur in coastal tract of Odisha, the Sundarban area of West Bengal, the central portion of North Bengal, and the southeast coast of Tamil Nadu.^[7]

Entisols

Entisols are also well spread (in association with Inceptisols) with representation in each federal state wherever there are depositions of alluvium, particularly along the riverbank and very shallow soils on hilltops, side slopes, plateaus, and eroded surfaces. These soils are spread over 67.67-million hectare area. Entisols, although reported from different parts of the country, are strikingly different in the Deccan basalt area compared to those in the IGP and/or coastal plains. More than 66% soils in this order are susceptible to water erosion, whereas almost 18% are estimated to be susceptible to wind erosion. The Entisols (Lithic Ustorthents) in the hilly forests developed from basalts are shallow, smectitic, and black in colour, whereas those in the IGP are very deep and often loamy to sandy/silty in texture grown mainly for paddy, wheat, and maize. Entisols in the coastal areas and deserts are Psammments containing sand throughout the soil depth. Acid sulfate soils discussed in detail under Coastal Plains belong to Entisol (Sulfa Aquent). These soils occupy second position (25%) after Inceptisols in India. Western states of Rajasthan and Maharashtra with semiarid climate have the highest coverage of this soil order. Crops like pearl millet, sorghum, and mustard are raised on these soils. Predominantly rainfed agriculture in these states leads to very low agricultural productivity. Irrigation development in many parts of these states has led to development of salinity. In high-rainfall zones, paddy is the only crop grown in these soils. Watershed management programs in this part of India have demonstrated how effectively the resources can be utilized for sustaining productivity.

Alfisols

Alfisols are observed mainly in central, eastern, and Peninsular India (area: 45.22 million hectares). It is the third largest soil order of India occupying more than 16% of area and spread well across the length and breadth of the country. Alfisols are of varied types, and those from

high-rainfall regions are acidic and poor in nutrients. Forest soils of the Himalayas,^[8] Western and Eastern Ghats, Kerala, and Mysore Plateau have high organic matter. It has been observed that the Alfisols are more acidic and have more clay and kaolin than the Mollisols. Occurrence of such soils suggests that the Alfisols (under sparse forest) are more weathered than Mollisols due to better water influx in the former. In many Alfisols of the IGP, clay increases with depth. The ratio of clay content in the clay-rich Bt horizon to that of the A horizon is >1.2 , which suggests that these soils are fairly well developed. These soils develop on stable landscapes with the concomitant and simultaneous erosion (degradation) and deposition (aggradation). There are cases where the successive horizons even in a restricted part of soil profile result from progressive alteration *in situ*, especially in subtropical regions of India.^[9]

Aridisols

Most of the Aridisols (14.22 million hectares) are located in western part of the country comprising the Great Indian Desert and the Kutch region. Aridisols are known to form under limited water availability wherein plant growth, leaching of salts, and soil formation are restricted. In India, Aridisols are largely confined to the vast contiguous Indian Desert in Rajasthan (58%) and Gujarat (12%) and to small parts of Punjab and Haryana. However, peninsular Indian states of AP and Karnataka together constitute more than 16% of area under Aridisols. The soils suffer from different kinds of degradation like wind erosion, salinity, sodicity, and pan formation such as petrocalcic and petrogypsic.

A major portion of the region consists of sand dunes and undulating sandy plains where water is a major constraint. The soils, in general, are capable of retaining only a limited amount of water and as such are droughty and prone to deep percolation losses of water received as rainfall or from canal irrigation. The fertility status is poor especially with respect to nitrogen and phosphorus due to high temperature and precipitation of applied phosphatic fertilizers as monocalcium phosphate, dicalcium phosphate, and tricalcium phosphate. Once irrigated and managed well, these soils have high potential for growing two crops in a year.

Mollisols

In contrast to the generally observed non-acidic and less weathered Mollisols in temperate semiarid and humid climate, acidic and fairly weathered Mollisols on Deccan basalt occur in hills of the Satpura Range of MP and the Western Ghats of Maharashtra under forest cover in the prevailing tropical humid climatic conditions.^[10] High rainfall and resultant water erosion degrade these soils. The formation of Mollisols in the zeolitized basaltic landscape over millions of years and their persistence in central and western India demonstrate that the quality of parent materials prevents the transformation of smectite to kaolin, helps in

the retention of adequate amount of smectite, and provides continuous supply of bases (Ca^{2+} ions) required for the formation of Mollisols even under tropical humid climate. These soils occupy the last position with less than 1% share in the country.^[11]

Ultisols

Ultisols are concentrated in the high-rainfall areas of the northeastern region and Kerala. Ultisols are found in the humid tropical areas of Kerala, southernmost tip of Tamil Nadu, Karnataka, and all the northeastern states where sub-surface kandic horizon is observed due to persistent high rainfall and temperature and a leaching environment. These soils are highly acidic in nature, poor in bases and major and minor nutrients, and prone to different forms of erosion. By virtue of being generally under forests and plantation crops, these soils are rich in organic matter. Eroded forms of these soils deposited in valleys are generally grown for paddy with the help of high-input management.^[7]

Ultisols in the humid tropical climate are dominantly clayey, and clay skins are difficult to be identified in the field in the northeastern part of India. However, the soils in the Western Ghats show evidence of translocation and accumulation of clay in the form of clay skins.^[11] Ultisols in Arunachal Pradesh show uniformity of parent materials. The clay distribution as a function of depth indicates that these soils are fairly well developed.

The soils are generally deficient in nitrogen and phosphorus but are well supplied with K. They are high in acid-soluble ferric oxide as compared to aluminum oxide. They are poor in organic matter and lime contents. These soils are cultivated intensively for a large variety of crops, including paddy, tea, coffee, cardamom, and cocoa, using heavy doses of organic manures and artificial fertilizers under irrigation conditions. Shifting agriculture is practiced in such soils.

Vertisols

Vertisols in India are a very important group of soils as the extent of their occurrence is just next to Australia and upon its proper management depends on the crop productivity in major part of semiarid tropical India. In India, the majority of the Vertisols are developed in the alluvium of weathering Deccan basalt in the states of Maharashtra, MP, Chhattisgarh, AP, Telangana, Karnataka, Gujarat, and Rajasthan. Additionally, outside the Deccan basalt region of the Peninsula, Vertisols are present in small patches in the states of Bihar, Odisha, West Bengal, and Kerala. Almost 65% of area under Vertisols is estimated to be prone to water erosion and other forms of degradation.

The arid and semiarid regions of India are dominated by Vertisols and their intergrades. About 80% of these soils form typical soils in central Peninsula. These soils are found to be spatially associated with red ferruginous soils. These

two soils occur in toposequence with red soils on crests and pediments and the black soils on foot slopes and in valleys and depressions. However, occurrence of such soils in close association under almost similar topographical situations is also reported.^[11] Vertisols are reported in the IGP.^[10]

The major constraints to crop production in Vertisols are their low workability. Sodidity is also a major productivity constraint arising out of low infiltration, poor drainage, and occasional moisture stress. These soils have high cation exchange capacity (30–50 [cmol(P+) kg⁻¹]), high base status, and high contents of exchangeable calcium and magnesium. They are, however, poor in organic matter, nitrogen, sulfur, and available phosphorus. These soils are predominantly used for growing cotton, soybean, maize, pigeon pea, millet, and sorghum in the states of MP, AP, Gujarat, and Maharashtra.^[7]

CONCLUSION

The SRM project undertaken on 1:1 million scale generated a rational and reliable soil information system of the country compatible with various soil information systems existing globally. This facilitated identifying soil characteristics including their problems and potentials. The soil information system so developed becomes a reliable component for recommending crop advisories which, if integrated with climatic and socioeconomic components, could ensure scientific land use planning.

Indigenous Soil Management

Karl Herweg

Centre for Development and Environment (CDE), Institute of Geography,
University of Bern, Bern, Switzerland

Abstract

Former approaches to technology transfer tried to identify a problem and to respond to it. This not only has improved soil management but has also been accompanied by major setbacks in the sense that adoption of alien technologies often ignored socioeconomic aspects and turned out to be costly or difficult to accept at the social level. Approaches, therefore, focus on incremental adaptation of technologies rather than on adoption, i.e., understanding indigenous farming practices to guide sustainable land use development. This does not mean that indigenous knowledge always provides the solution. Rapid changes in the socioeconomic, political, and biophysical environments put indigenous knowledge systems under tremendous pressure and do not give them time to adapt themselves to the changes. But learning about local knowledge, recognizing indigenous practices and their functions, and then trying to improve soil management together with local farmers, researchers, and external advisors means making the best use of all available knowledge systems.

INTRODUCTION

“Indigenous” or “local” knowledge is unique to a given culture or society, in contrast to external knowledge that is generated within the international system of universities, research institutes, and private firms.^[1] However, virtually all indigenous knowledge systems have been exposed to external influence, be it during the eras of colonization or development cooperation, owing to migration and trading and international training of local experts, or through the mass media. What is termed as indigenous knowledge has already incorporated suitable components from external knowledge systems, or, in other words, introduced technologies have been indigenized.^[2] Thus, in this entry, the term “indigenous soil management” refers to agro-pastoral or mixed small-holder farming systems with low external agricultural inputs^[3] rather than to the rare cases that may be absolutely isolated from the outside world.

INTEGRATED SOIL MANAGEMENT

The term “indigenous soil management” indicates a typical scientific approach. In the reality confronted by land users, an equivalent term for soil management as such may not exist, because soil is always integrated in an overall farming system, e.g., to produce food and fodder. Thus, indigenous soil management should be seen in the framework of a land management system.^[4]

Indigenous knowledge systems are highly site specific.^[4,5] They undergo permanent adaptation in response to local

socioeconomic and environmental changes and thus always imply an aspect of innovation. Apart from its site specificity, indigenous soil management system may best be characterized as multifunctional, flexible, and dynamic.^[2,6,7] In [Table 1](#), examples of various indigenous soil management options are given.

Multifunctionality

Each household pursues its own livelihood strategy, and land users apply a range of land management practices to achieve their goals. Each practice may involve the management of soils besides other components such as water, crops, animals, forests, and human resources. Each practice usually serves more than one purpose, e.g., crop production and resource protection.^[6,7]

Flexibility and Dynamism

Indigenous soil and land management usually is flexible and dynamic in several aspects. Each practice responds to one or more specific problems (soil erosion, low production, pests, etc.) at a specific location (steep slope, valley bottom, communal land, etc.), as perceived by a land user with specific experience, capabilities, and options to react. In addition, the positive impact and the side effects of a practice are permanently observed, and the practice is modified, if necessary, over time. This means that, depending on the variations in these factors, a practice will always look different, from one field to another, and from one farmer to another.^[6,7]

Table 1 Examples of indigenous soil management options.

Option	Main purposes	Area (reference source)
Working arrangements (sharecropping, animal fattening)	Overcome labor shortage, optimize timing of farming operations	Ethiopia ^[6,7]
Gradual build-up of terraces	Effective use of labor	Ethiopia ^[2,6,7]
Focusing only on locations with severe erosion	Effective use of labor	Ethiopia ^[6,7]
Joint decision-making among neighbors	Avoid pests as result of individual cropping patterns	Nepal ^[8]
Fallow	Recycling of nutrients, recovering of soil fertility	Africa, ^[2,9] Ethiopia, ^[4] South America, ^[10] Nepal ^[8]
Crop rotation, selection of crops to correspond with soil potential, use of nitrogen-fixing trees	Prevent exploitation of nutrients	Africa, ^[2,9] Ethiopia, ^[4] South America, ^[10] Nepal ^[8]
Manure (from fixed pens, open grazing, compost, crop residues, household waste, leaf litter, weeds)	Improve nutrient level and physical soil properties to provide better aeration, infiltration, water-holding capacity and soil moisture	Africa, ^[2,9] Ethiopia, ^[4] Kenya, ^[5] South America, ^[10] Nepal ^[8]
Mulching	Improve soil fertility, reduce evaporation	South America ^[10]
Soil burning	Improve infiltration and availability of nutrients	Ethiopia ^[6]
Trapping eroded soil	Improve soil fertility	Mexico ^[10]
Application of fertile silt from ponds and rivers	Improve soil fertility	Africa ^[2]
Temporary structures (trash lines)	Collect and redistribute fertile accumulation	Ethiopia ^[2,6,7]
Indigenous terraces and grass and vegetation strips	Collect and redistribute fertile accumulation	Ethiopia ^[2,6,7]
Water harvesting (drainage ditches, gully reclamation)	Conserve water/moisture	Africa, semiarid areas ^[2]
Crescent-shaped or rectangular embankments	Slow down runoff, increase infiltration	Africa, semiarid areas ^[2]
Ridging and infiltration pits (Zaï, tassa)	Break hard topsoil layers, increase infiltration	Africa, semiarid areas ^[2]

INDIGENOUS SOIL CLASSIFICATIONS AND FERTILITY INDICATORS

Indigenous soil classifications reflect land users' perceptions of land and soils, their potential for a specific purpose, and their spatial variability. Such classifications are usually well categorized and based on well-identified criteria, which typically incorporate diverse properties of soil or soil-related factors, e.g., texture, color, water-holding capacity, irrigation requirements, soil softness, drainage, fertility, and crop suitability.^[10] Soils are often classified according to their suitability for growing certain crops, based on vegetative, topographic, and microclimatic indicators.

Soil fertility is considered a dynamic characteristic, not an inherent quality.^[10] In local terms, soil fertility may, for instance, be connected with manure requirements, but interestingly, it is not globally attributed to nutrient availability. For example, water-holding capacity (in semiarid areas) and permeability and drainage of the soils (in subhumid areas) may be considered more important than the overall nutrient status. Also, socioeconomic terms such as "workability" are used to describe a fertile soil, e.g., if the soil can be prepared with a few tillage operations only, if tillage is relatively easy, or if labor requirements are low. Although

indigenous soil classifications and indicators of soil fertility are highly site specific, soil texture and color are the most common factors in indigenous knowledge systems to distinguish soils of different quality.^[10]

Local knowledge of soil–plant–fauna relationships is used to select crop varieties or crop rotations suitable to a specific soil. Soil heterogeneity is acknowledged and advantageously used and not eliminated by fertilization. The choice of crops for each soil is not necessarily unanimous, but depends largely on the individual experience and interest of the land user.^[10] Local plants that indicate soil fertility are as common as the knowledge of plants that are beneficial for improving soil fertility. The range of indigenous biological indicators is wide, e.g., the appearance of mauls in the accumulation of indigenous terraces, in combination with grass production on the terraces, is known to be an indicator of improved soil fertility.^[7]

INDIGENOUS SOIL MANAGEMENT PRACTICES

Continuous farming or animal grazing affects soil in many ways; e.g., monocropping and soil erosion diminish nutrients and organic matter; soil erosion changes soil depth,

texture, structure, and the capacity to store water and nutrients; irrigation in semiarid areas increases the salt content. Indigenous soil management practices try to prevent or minimize degradation processes and focus on managing labor, soil fertility (soil nutrients and organic matter), and both the excess and shortage of water.^[8]

Managing Limited Labor

Wealthy farmers have a greater labor force, more draught power, and a greater range of soil management options compared to relatively poor land users. Limited labor and transport facilities usually result in intensively used land around the homesteads and decreasing intensity toward the most distant plots. Shortage of labor often forces farmers to rely on each other and to make sharecropping, animal fattening, and other arrangements.^[6,7] Decisions are often made together with neighbors or in the community, because individual strategies can lead to severe problems; e.g., a single farmer who decides to plant early will attract all the pests to his fields, or a single field that is left fallow will be a refuge for pests that affect all neighboring plots.^[8] Local societies have a number of working arrangements to overcome labor shortages, resolve conflicts over scarce resources, and use optimum timing for land preparation, weeding, and other farming activities.^[6,7]

Managing Soil Fertility and Soil Water

Probably the most common way of recycling nutrients and reclaiming land after a period of nutrient and water exploitation is to leave it “fallow” until its fertility has recovered. However, increasing population and animal pressure, fragmentation of the land, insecure land tenure, and other factors force land users to shorten their fallow periods and to look for alternatives,^[2,4,8–10] e.g., crop rotation (e.g., cereals and legumes), selection of crops corresponding to the potential of the soil, and the use of nitrogen-fixing trees are common methods for preventing exploitation of nutrients. A number of indigenous practices contribute to improved nutrient levels and physical soil properties that provide better aeration, infiltration, water-holding capacity, and soil moisture; e.g., the organic matter content can be improved by manure, if the herd size is sufficient, if manure can be purchased from pastoralists, or if the manure is not used for other purposes (fuel, construction, to protect seeds from diseases, etc.). Application of manure requires improved weed control. The highest concentration of manure is found around the homesteads (fixed pens). Distant plots can be improved through mobile pens and open grazing. Other sources of organic matter can include incorporation of compost, household waste, leaf litter, weeds (uprooted and burned) in the soil, and crop residues left after harvesting or disseminated as mulch. Again, availability is the limiting factor, as crop residues are frequently used as fodder. It is also common

to carry fertile silt from community ponds back to improve the cultivated fields. Soil burning—together with dung and other organic matter—may improve water infiltration and availability of nutrients on a rather short-term basis.

Particularly in arid and semiarid areas, the shortage of water is the greatest constraint on production. Effective indigenous water harvesting practices include ridging and infiltration pits (zaï, tassa) that break hard layers in the topsoil, crescent or rectangular embankments that allow slow movement of runoff and better infiltration, and mulch that reduces evaporation. Drainage ditches and gully reclamation measures help control erosion in subhumid areas and harvest water in semiarid areas. Indigenous terraces and grass and vegetation strips are used to enforce the accumulation of fertile topsoil and to prevent further decline of soil fertility.^[2] But unlike introduced soil and water conservation (SWC) structures such as soil bunds, indigenous SWC measures are built from material that can best be spared, such as stones or brushes, instead of fertile soil. In addition, indigenous SWC measures rarely cover the entire slope but concentrate on “hot spots,” where severe soil erosion is expected or where soils are particularly shallow (sedimentation management).^[10] Indigenous SWC is often a mixture of temporary structures (e.g., trash lines)—i.e., scheduled for removal to redistribute the fertile accumulation—and permanent structures (e.g., stone bunds serving at the same time as field borders or fences). Probably the greatest difference between introduced and indigenous measures is that the latter are rarely constructed in one go, but are gradually built up in the course of other farming activities such as plowing and weeding.^[2,6,7]

CONCLUSION

Former approaches to technology transfer tried to identify a problem, such as declining soil fertility, soil degradation, and pests, and to respond to it, e.g., through on-station research and dissemination of technologies. This not only has improved soil management but has also been accompanied by major setbacks in the sense that adoption of alien technologies often ignored socioeconomic aspects and turned out to be costly or difficult to accept at the social level. Approaches, therefore, focus on incremental adaptation of technologies rather than adoption, i.e., understanding indigenous farming practices to guide sustainable land use development.^[10] This does not mean that indigenous knowledge always provides the solution. Rapid changes in the socioeconomic, political, and biophysical environments put indigenous knowledge systems under tremendous pressure and do not give them time to adapt themselves to the changes. But learning about local knowledge, recognizing indigenous practices and their functions, and then trying to improve soil management together with local farmers, researchers, and external advisors means making the best use of all available knowledge systems.

Abstract

The Indo-Gangetic Plain (IGP) is largest fluvial plains in the world. In India, it occupies 13% of the total geographical area and produces nearly 50% food grain production of the country. The soils are under tremendous stress because of high demographic pressure and intensive cultivation, resulting in declining soil quality and crop productivity. To arrest this, the detailed information of soils of IGP and their characterization, constraints, and potentials were synthesized, which may be useful in sustainable land resource management. The soils of IGP varied widely in its extent, nature, and characteristics. The dominant soil belongs to orders Inceptisols (68%), Entisols (23.2%), and Alfisols (5.2%). The soil map of IGP was generated by identifying 185 subgroup associations, and the dominant subgroups are Typic Ustochrepts, Typic Ustifluvents, Fluventic Ustochrepts, Aeric Haplaquepts, Typic Ustipsamments, and Udic Ustochrepts. The Piedmont plain of IGP has deep, well-drained, loamy/sandy loam, mildly to moderately alkaline soils medium in organic carbon (OC), whereas Tarai region accounts well-drained, loamy soils rich in OC. Soils of semiarid aeolian/aeofluvial plains are sandy/coarse-loamy, saline/sodic, calcareous with low nutrient- and water-holding capacity. Soils of alluvial plains vary widely in texture, drainage, and fertility. Poor drainage, occasional flooding, and salinity/sodicity are the major constraints affecting crop productivity in upper and middle alluvial plains. Lower alluvial plains (Bengal Basin) suffer from waterlogging, frequent flooding, low nutrient status, and salinity. Appropriate land management practices and land use options are needed to ameliorate these constraints and sustain agricultural productivity.

INTRODUCTION

Soil is a limited and non-renewable resource, and its continuous cultivation even with best technologies and skills results in deterioration of its quality.^[1] About 57% of the country land area is under agriculture as against the world average of 11.5%. Major land use changes have occurred after independence when net sown area increased from 118.75 mha in 1950–1951 to 140.0 mha by 1970–1971, 143.0 mha by 1991–1992, and 140.8 mha by 2011–2012. Agricultural interstratifications and high population pressure including Green Revolution era and beyond have caused degradation of various forms. Harmonized data have put total degraded area at 121 mha—with water-induced erosion being the major form followed

by chemical degradation, wind erosion, and physical degradation.^[2]

The Indo-Gangetic Plain (IGP) region is the food bowl of the country and produces nearly half of food grains in India. Average yield of food grains (3314 kg ha^{-1}) is far better than that of the country as a whole (1860 kg ha^{-1})^[3] with high cropping intensity ranging from 133% to 188%. The vast plain is witnessing degradation of natural ecosystem, such as soil and water, and declining productivity.^[4] Sustainability of different production systems is under threat with several reports indicating fatigue of the natural resources.^[5,6]

In view of increased demands for food and fiber and limited scope for bringing new area under plough, it is imperative to have comprehensive knowledge about soil

and land resources. It will help to land management and land use options for improving crop productivity and soil and environmental quality. This entry briefly describes the distribution of soils under different physiographic and agroecological regions (AERs) in IGP with analysis of their potentials and constraints for scientific land use.^[7]

GEOGRAPHIC SETTINGS

The IGP is one of the most extensive fluvial plains of the world. It is situated between Gurdaspur district (Punjab) in the west and Jalpaiguri district (West Bengal) in the east, is extending to west Assam in the northeast, lies between 21° 45' to 31° 30' N latitude and 74° 15' to 91° 30' E longitude, and covers an area of 44 mha (Fig. 1). These are aggradational plains formed by the rivers the Ganges and the Brahmaputra and their tributaries. They include Indus plain, Rajasthan plain, Punjab plain, Ganga plain, and Brahmaputra valley. It covers the states of Punjab, Haryana, Delhi, Uttar Pradesh (UP), Uttarakhand, Bihar, West Bengal, Assam, and some parts of adjoining states.^[8]

There is a wide variation in climate, land use, and soils in the region conditions. Climate ranges from arid to semi-arid in the west to humid to perhumid in the east.^[8,9] The rice and wheat are the main crops apart from pulses, oilseeds, cash crops, and horticultural crops. Barring the area in the extreme west (Rajasthan), rice (*Oryza*

sativa L.) is grown throughout the IGP. However, in the extreme east, wheat (*Triticum estivum* L.) is not preferred due to shorter winters. Other crops grown are sugarcane (*Saccharum officinarum* L.), cotton (*Gossypium hirsutum* L.), mustard (*Brassica juncea* L.), safflower (*Carthamus tinctorius* L.), pearl millet (*Pennisetum glaucum* L.), potato (*Solanum tuberosum* L.), and groundnut (*Arachis hypogea* L.).

Geological Age of Soils

History

The IGP ranks as one of the most extensive fluvial plains of the world. The deposit of this tract represents the last chapter of earth's history. It came into existence due to collision of the Indian and Chinese plates during Middle Miocene.^[10] The Indian plate is moving at the rate of 2–5 cm yr⁻¹ toward the north and forming the world's highest mountain range on its border. The north–south compression generated throughout the plate ensures that it is continuously under stress and provides the basic resource of accumulating strain in the fractured zones.^[11] The fluvial deposits and landforms of the IGP have been influenced by the stresses directed toward north and north-east. The major rivers of the IGP have changed their courses and are flowing in southeast and easterly directions with convexity toward the southeast, which is strikingly similar to the arcuate pattern of the major thrusts bordering

Fig. 1 Extent of IGP, India.

the IGP.^[12] Thus, the IGP shows a series of terraces, bars, and meandering scars, resulting in microhigh and microlow areas on the apparently smooth topography.^[13–15] The IGP is tectonically active, and the major sedimentation is taking place from large river systems of the IGP. The IGP is mainly developed by the alluvium of Indus, Yamuna, Ganga, Ramganga, Ghagra, Rapti, Gandak, Bhagirathi, Silai, Damodar, Ajay, and Kosi rivers. Geophysical surveys and deep drilling by the Oil and Natural Gas Commission of India^[16,17] suggest that the IGP is a vast asymmetric trough with maximum thickness of 10,000 m that thins out to the south. The nature and properties of the alluvium vary in texture from sandy to clayey, calcareous to non-calcareous, and acidic to alkaline. Though the overall topographic situation remains fairly uniform with elevations of 150 m amsl (meter above mean sea level) in the Bengal Basin and 300 m amsl in the Punjab plain, local geographic variations are significant.^[18]

PHYSIOGRAPHY AND AGROECOLOGICAL SUBREGIONS (AESRs)

The IGP is basically a riverine plain, commonly known as Indo-Gangetic alluvial Plains that are composed of featureless landform on broad scale and variations at local conditions. The elevation ranges from 150 msl to 300 msl.^[14] Broadly, the IGP is divided into six major physiographic units based on the landform analysis. Alluvial plains occupied largest area (69% of TGA) followed by transitional aeofluvial plains (19.5%), aeolian plain (5.4%), piedmont plain (4.5%), Brahmaputra Valley (0.6%), and Tarai region (0.5%).

The region reflects a close relationship between physiography–soils–climate and vegetation. Accordingly, it represents 8 AERs, 17 AESRs (Fig. 2), and 6 bioclimatic regions of the country, depending upon major physiography, climate, and length of growing period (LGP).^[7,8,19,20]

SOILS OF IGP

The soil resource information available at state level at association of subgroups^[21] was integrated in Geographic Information System (GIS) by using GIS ArcGIS-9.2 software (ArcGIS-9.2 is version) and generated the soil map of IGP (Fig. 3). The soils of the IGP varies widely in their extent, nature, and characteristics. These belong to 5 orders, 12 suborders, 18 great groups, and 36 dominant subgroups. Soils of order Inceptisols account for largest area (68.0%), followed by Entisols (23.2%), Alfisols (5.2%), Aridisols (3.0%), Mollisols (0.31%), and others (0.24%; Fig. 4). The areal extent of dominant subgroups occurring in IGP region is given in Table 1. On the basis of physiographic delineation, climate, vegetation, and parent material, the soil resources of IGP are described under the following subheads.

SOILS OF PIEDMONT PLAIN AND TARAI REGION

The soils of this region occupy an area of 2.8 mha in the states of Punjab, Haryana, UP, and southern part of Uttarakhand.^[22–26] The dominant landscape of the region is represented by gently to very gently sloping and nearly level plain. The soils mainly belong to Typic Ustifluvents, Typic Ustipsamments, Aquic/Typic Udipsamments, Typic Haplaquents, Aquic Udifluvents, Typic Udorthents, and Typic Ustorthents subgroups of Entisols; Typic/Fluventic Haplustepts, Typic/Fluventic Eutrudepts/Fluventic Haplustepts of Inceptisols; and Udic-Typic Haplustolls of Mollisols.^[21] The soils, developed on alluvium, are deep to moderately deep, loamy, and calcareous. Soils of Tarai region are high in organic carbon (OC) content.

The region pertains to AER-9. The agroclimate is characterized by hot dry subhumid to semiarid transition with dry summers and cool winters with annual rainfall ranges from 700 to 1200 mm. LGP is 150–180 days.^[7] The natural vegetation consists of northern tropical dry mixed deciduous forest. Most of the area is under rainfed agriculture. The main crops grown are maize, pigeon pea, rice, sugarcane, and cotton (in small patches) during *kharif* and wheat, barley, mustard, and lentil during *rabi* season.

Potentials and Constraints

Soils of Tarai region are suitable to grow high-value commercial crops and medicinal plants. Fine loamy soils have problems of permeability. Water erosion during rainy season through seasonal streams (Choes) is a constraint in kandi areas. Plantation of commercial trees, e.g., Poplar, *Dalbergia sissoo*, has wide scope in these areas.

SOILS OF ALLUVIAL PLAIN

These soils occupy an area of 34.2 mha in the states of Punjab, Haryana, UP, Bihar, and West Bengal.^[23,25–28] It is agriculturally important belt and popularly known as “Green Bowl” of the country. The dominant soils belong to Typic Haplustepts, Fluventic Haplustepts, Typic Psammaquents, Typic/Aeric Fluvaquents, Typic/Ustic Torripsamments, Aquic/Typic Ustipsamments, Aquic/Typic Ustifluvents, and Typic Ustorthents subgroups of Entisols; Aeric Halaquents, Typic/Vertic/Fluventic Haplustepts, Aquic/Fluventic/Typic/Vertic Haplustepts, Dystric Eutrudepts and Dystric Eutrudepts of Inceptisols; Fluventic/Typic/Vertic/Ustic Camborthids of Aridisols; and Typic Haplustalfs, Typic Natrustalfs, and Typic/Aeric/Vertic Ochraqualfs of Alfisols.^[21]

These soils are very deep, light to dark yellowish brown/brown, well-drained to moderately well-drained, loamy/fine loamy, moderately to strongly alkaline, moderate to highly calcareous, and low to medium in available nitrogen (N) and phosphorus (P) content but medium to high in

Fig. 2 Agroecological subregion (revised) map of IGP.

Source: From Mandal, Mandal, et al.^[19] ©2014.

available potassium. The deficiency of zinc (Zn), copper, and manganese has been reported in some intensively cultivated areas. Some soils of this region are reported problem of salinity.^[29] The formation of hardpan in subsurface soils has been noted in some soils of rice-wheat cropping system areas.^[30] Some low-lying areas have problem of imperfect or poor drainage and occasional flooding. Soils of northern IGP (eastern UP and Bihar state) region is, in general, deep, fine loamy/fine silty.

The low-lying tracts of Varanasi, Ghazipur, and Ballia districts of UP are of fine loamy, Aeric Ochraqualfs,^[31] while Bihar plains had Aeric Haplaquepts/Typic Haplaquepts and Ustifluvents soils that show wide variation in drainage. Occasional flooding and imperfect drainage, fine soil texture, and medium to low fertility [available P and sulfur (S)] are the problems of eastern part of the IGP. Salinity, strong alkalinity, and calcareousness induce nutrient imbalance.^[20,32] Soils of Bengal Basin (in parts of

Fig. 3 The soil map of IGP, India.

Hooghly, Murshidabad, and Bardhaman districts) are very deep, fine loamy, mildly to moderately alkaline Fluvaquepts/Fluventic Eutrudepts and Vertic Ochraqualfs.^[20] It is estimated that about 69% carbon in the IGP soils is confined to upper 40 cm soil layer, where C stock ranges from 8.5 to 15.2 t C ha⁻¹.^[33] Soil OC can be enhanced following introduction of pulses in rice–wheat cropping system and organic nutrient management practices.^[32,34]

The soils represent AERs 4, 9, 13, and 15. The mean annual rainfall ranges from 500 mm (in North West) to as high as 1400 mm in eastern parts. The mean annual temperature varies from 25°C to 26°C. Accordingly the LGP varied from 90–150 days (AESRs 4.1 and 4.3) to 150–180 days (AESRs 9.1 and 9.2) and 180–>210 days (AESRs 13.1, 13.2, 15.1, and 15.3, 18.5).^[7] The natural vegetation consists of tropical dry deciduous and tropical thorn forests in west and central parts and tropical moist and deciduous forests in east. The area is mostly irrigated due to vast network of canals and tube wells. Cotton (in northwest belt), sugarcane, sunflower, beans, rice (60-day duration),

green gram, rapeseeds/mustard, etc. are grown. In AERs 13 and 15, cropping system is mainly rice-based due to high rainfall, particularly in the Bengal plains. In rabi season, rice, jute, pulses, and oilseeds are grown on stored/residual soil moisture. Wheat crop is replacing other crops in eastern parts.

Potentials and Constraints

Majority of soils are suitable for growing region-specific crops. Diversification of cropping system by introducing pulses and oilseed crops may narrow down the gap of supply and demand of these crops. Potato–sugarcane–jute in the middle and eastern region has great potentiality to enhance income of the farmers.

Among the constraints, flooding and imperfect drainage conditions, salinity, and/or sodicity throughout the north-west, central, and some parts of central, eastern parts adversely affect the crop yields. Rice soils have developed subsurface compaction. The deficiency of N, P, S, Zn, etc.

Fig. 4 Spatial distribution of soil orders in the IGP, India

are widespread in intensively cultivated areas. Sandy soils along the river and flood plains suffer due to poor soil fertility. Over exploitation of underground water for irrigation in rice–wheat growing areas has caused decline in water table at an alarming rates.

SOILS OF ARID AEOLIAN PLAIN

Southern part of Punjab, Haryana, and some part of Rajasthan states^[24,25,35] occupy an area of 2.65 mha. The dominant soils belong to Typic Torripsamments, Ustic Torripsamments/Typic Torrifluvents, and Typic Torriorrhents, Typic/Fluventic Camborthids/Typic Haplocalcids.^[21] These soils are deep, sandy to coarse loamy, low in OC, high in pH and electrical conductivity, and calcareous in nature.

These soils belong to AER 2 and AESR 2.3a (the region represents typic hot and arid climate characterized by hot and dry summers and cool and dry winters). The mean annual rainfall is <400 mm that too is concentrated in few events of high intensity. The LGP is <90 days.^[7] The natural vegetation comprises of sparse sporadic tropical thorn forests. Monocropping of drought resistant, short duration

crops such as pearl millet, sorghum (fodder) and pulses are grown under traditional farming practices. Introduction of irrigation through Indira Gandhi canal encouraged farmers to grow crops like wheat, cotton, mustard, and even sugarcane in some areas. Fruits like ber and kinnow (*Hybrid citrus*) are also grown by some farmers.

Potentials and Constraints

The soils in the ecoregion are potentially fertile because of abundant primary minerals. Severe dry hot climate coupled with strong sandy storms in the early growing stage of cotton and other kharif crops severely affects the germination and young seedlings of crops. Sandy soils suffer due to low fertility and water-holding capacity. Salinity develops due to water logging condition near canal.

SOILS OF SEMIARID TRANSITIONAL AEOFLUVIAL PLAIN

The soils of the region comprises of southern–western parts of Punjab, and northern–western parts of Haryana^[23,25]

Table 1 Areal extent of soil subgroups in IGP.

Soil subgroups	Area (mha)	% of TGA	Soil subgroups	Area (mha)	% of TGA
Inceptisols			Entisols

Total	2,118.7	4.82	Udic Haplustolls	127	0.28
			Total	127	0.28
Other soil orders				98.8	0.22
Other miscellaneous land				3,605.8	9.11
Total geographical area of IGP				44,000	100

occupy an area of 9.57 mha. The dominant soils belong to Typic/Ustic Torripsamments, Typic Ustifluvents, Typic Psammaquents, Aquic Ustipsamments, Typic/Lithic Haplustepts, and Lithic/Typic/Ustic Camborthids/Camborthids.^[21] These soils are very deep and sandy/coarse loamy. These soils are underlain by salt-rich material like gypsum, calcite, and dolomite. Soils of arid and semiarid climate are prone to be calcareous and sodic due to low levels of OC.^[21]

These soils pertain to AER 4, with mean annual temperature of 25°C. The annual rainfall varies from 400 to 600 mm in different years. LGP is between 90 and 120 days.^[7,9] The natural vegetation consists of tropical dry deciduous and tropical thorn forest. These soils belong to dry region with rainfall < 600 mm, but the majority of areas are cultivated by levelling the sand dunes and irrigating with the network of canals. These areas are cultivated for wheat, cotton, gram, pulses, and oilseeds, and even rice has been introduced in some area.

Potentials and Constraints

These soils have very high potential for pulses and oilseed crops. These soils are coarse-textured poor soil fertility, nutrient-supplying capacity, and available water-holding capacity. Provision of irrigation has given rise to formation of saline and sodic problems. Use of poor quality of groundwater for irrigation further aggravates the problem of salinity in the region. Many areas face inadequate supply of irrigation water at tails of canals during peak periods of plant growth.

SOILS OF ASSAM (BRAHMAPUTRA) VALLEY

Teesta and Barak valley soils belong to Aeric/Typic Fluvaquents, Aquic/Typic Ustifluvents/Udofluvents, and Aquic/Typic Udipsamments of Entisols, Typic Halaquepts/Dystric Eutrudepts, Udic Haplustepts, Fluventic/Humic Dystrudepts of Inceptisols and Typic Hapludalfs.^[21,36,37] The soils

developed on alluvial flood plains are clayey, moderately to strongly acidic in reaction with low base saturation, but relatively rich in OC.^[36,38] The soil depth ranges from shallow (on steeply sloping hills) to moderately deep (terrace soils) to deep in valleys. Low-lying soils are deep, poorly drained, very slowly permeable, fine clayey over loamy.

These soils belong to AER 15 and AESR 15.3. Mean annual temperature is in the range of 24–25°C. The mean annual rainfall ranges from 2000 to 3200 mm. LGP is more than 300 days.^[7,20] The natural vegetation comprises of tropical moist deciduous to semievergreen, riverine Savannah and bamboo cane forests. The area is intensively cultivated under rainfed rice and jute and millets. Rice is cultivated throughout the year. The plantation crops like tea, pineapple, rubber, and banana are grown under favorable climatic conditions.

Potentials and Constraints

The acidic soils high in humus are most suitable high-value crops for tea, coffee, and rubber plantation. Shallow soil depths on hill slopes and frequent flooding in low-lying areas particularly in monsoon season are major limitation. High rainfall causes excessive leaching of bases, resulting in poor base status.

CONCLUSION

The IGP in India covers 44 mha and extends from Punjab, Haryana, Delhi, UP, Uttarakhand, Bihar, West Bengal, Assam, and northeastern states. It is an agriculturally potential area contributing about half of the food production of the country from 13% of total geographical area. Broadly, the IGP is subdivided into six major physiographic units with alluvial plains and transitional aeofluvial plains being the major ones. Although the soils of the IGP belong to five orders, Inceptisols and Entisols cover about 91% of total area under soils. Soil map of the region has 185 mapping units of subgroups in association. The soils belong to 37 dominant subgroups, but two-third area is under four soil subgroups, namely Typic Haplustepts (36%), Typic Ustifluvents (9%), Aeris Fluvaquents (7%), and Typic Ustipsamments (6%). The Piedmont plains and Tarai region represent deep, well-drained, and coarse-textured soils, while Tarai plains account loamy soils rich in OC. Major area of the IGP is covered under Alluvial plains that have medium to high productivity potentials for a variety of crops. Major constraints in alluvial plain are salinity/sodicity, drainage, and flooding, which increase from upper to lower plains. Continuous cultivation without scientific land use and management has resulted in soil fatigue and low productivity. Proper soil and crop management practices are required to ameliorate soil physical, chemical, and biological condition and improve soil fertility. Soil-site-based land use options, integrated nutrient management,

conservation agriculture, and groundwater augmentation should be adopted to address issues of sustainability in this food bowl of the country. The soil information presented in this entry provides an overview in reference to AESR, which may contribute to better land resource management and land use planning on sustainable basis.

Industrial Waste

Warren Dick

School of Natural Resources, Ohio State University, Wooster, Ohio, U.S.A.

Abstract

Large amounts of industrial wastes are either disposed in a planned manner or simply allowed to disperse into the environment (e.g., carbon dioxide, because of the combustion of fossil fuels). However, there are only a few places where disposal can be done on (or in) the land, dumped in water bodies such as the oceans, or incinerated. Ocean dumping has been outlawed or severely curtailed in many of the more developed countries. Incineration is also often opposed because during combustion of the waste, there is potential to create even more toxic materials such as dioxins. Therefore, the only remaining disposal area is the land. This can be in dedicated landfills. Alternatively, many industrial by-products are being viewed as having potential beneficial properties that can be captured either as a recycled material or land-applied as a soil amendment. Each of these options must be carefully researched to avoid the creation of a new problem by solving an existing problem.

INTRODUCTION

There is no universally accepted definition of industrial waste. Common sense suggests industrial wastes are any materials created or left over as a result of industrial activities to produce durable and non-durable goods. In a utopian world, we would be 100% efficient in the use of raw materials and products, which, once manufactured, would serve their purpose and then simply vanish with no need for disposal.

Unfortunately, although we are not operating in the same grossly inefficient way we did during the peak of the Industrial Revolution, we are generating millions of metric tons of industrial wastes every year. We will never achieve the utopian dream, but we can make it our goal to reduce the amount of industrial wastes and to properly dispose those materials that cannot be beneficially recycled. The first step toward achieving this goal is to identify the types of industrial activities and the wastes they create. Then processes and technologies can be designed such that they will either reduce the amounts of wastes created or recycle the wastes in ways that are environmentally safe and economically beneficial.

TYPES OF INDUSTRIAL PRODUCTS

Our modern lifestyle has generated an insatiable appetite for all types of manufactured products. In [Table 1](#), a list of industrial products is given. All these products generate industrial waste at some point in their life cycle. The type of wastes may be unique or be common to many different types of products. The major variables that affect the amounts and types of wastes for each product are the raw

materials used, the amount of processing required of the raw materials before a finished product is created, the relative toxicity of the processing materials, and the total amount of energy required during product manufacture.

TYPES OF INDUSTRIAL BY-PRODUCTS

The types of industrial by-products are as varied as there are industries to produce materials and goods for human consumption. However, there are several broad categories that can be identified and the information presented below is taken from the work of Miller et al.^[1]

Metal Refining and Processing

“Slags” are produced by iron and steel making. In 1995, 21 million metric tons were produced in United States. Slags are produced by addition of lime to furnaces to remove silicon impurities and are composed primarily of CaSiO_3 . About 60% of the slags produced are iron slags and 40% are steel slags. “Fine dusts” are fine airborne particulates collected from metal processing, refining, and fabricating industries. The most commonly encountered dusts are fines from the metal processing industry (especially from electric furnaces) and are primarily ferrous in nature with admixture of heavy metals. Approximately, five million metric tons per year are produced in United States and most are either recycled within the facility or used as landfill.

Mineral Processing

“Gypsum” ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) is produced as a by-product by a number of industries, most notably the phosphate fertilizer

Table 1 Census Bureau's industrial products overview covering manufactured durable and nondurable goods.

Industrial product category	Industrial product subcategory
Building materials	Clay construction
	Lumber and mill stocks
	Plumbing fixtures
	Refractories
Chemicals	Fertilizer materials
	Industrial gases
	Inorganic chemicals
	Paint and allied products
	Paint, varnish, and lacquer
	Pharmaceutical preparations
Consumer goods	Consumer electronics
	Electric housewares
	Household appliances
Electronics	Communication equipment
	Computers and office machines
	Electromedical equipment
	Fluorescent lamp ballasts
	Lighting fixtures
	Measurement instruments
	Semiconductors and components
	Switchgear and industrial controls
	Wiring devices
Food	Confectionery
	Fats and oils
	Flour milling
	Oilseed crushings
Glass	Flat glass
	Glass containers
	Glassware
Heavy machinery	Construction machinery
	Farm equipment
	Internal combustion engines
	Metalworking machinery
	Mining machinery
Industrial equipment	Air pollution control
	Antifriction bearings
	Fluid power
	Motors and generators
	Pumps and compressors
	Refrigeration and heating
	Steel drums and pails
	Vending machines

(Continued)

Table 1 Census Bureau's industrial products overview covering manufactured durable and nondurable goods. (Continued)

Industrial product category	Industrial product subcategory
Primary metals	Aluminum mill products
	Insulated wire and cable
	Iron and steel castings
	Non-ferrous castings
	Steel mill products
	Steel mill inventories
Textile and apparel	Apparel
	Broadwoven fabrics
	Carpets and rugs
	Cotton consumption
	Footwear (annual)
	Footwear (quarterly)
	Gloves and mittens
	Knit fabric production
	Bed and bath furnishings (sheets, pillowcases, and towels)
	Woolen consumption
Transportation	Yarn production
	Aerospace industry
	Civil aircraft and engines
	Truck trailers

Source: Adapted from U.S. Census Bureau.^[2]

industry, the pigment processing and electroplating industries, and the electricity generating industry. Large amount of gypsum are created during the processing of rock phosphate to produce phosphate fertilizer. Nearly 1 billion metric tons of "phosphogypsum" are stockpiled in the phosphate district of central Florida, where most of the commercial rock phosphate deposits are found in United States. A major concern related to phosphogypsum is the radioactivity that occurs because of the radioactive elements originating in the sedimentary phosphate deposits. "Cement kiln dust" is a fine material produced during manufacture of Portland cement, which involves heating lime and siliceous materials (clay and shale) to a molten state in rotary ovens or kilns. Dust in the exhaust is removed by filter units and is composed of fine feed material, cement, and sloughed refractory materials. In 1995, there were 118 facilities in 37 states producing 80 million metric tons of cement and approximately 3–5 million metric tons of kiln dust. "Tailings" are fines remaining after crushing and extraction of ores during mineral separation and refining. Many different separation and refining processes result in a wide range of materials such as the clayey phosphate slimes and the red muds of aluminum (Al) metal processing.

Coal Combustion By-Products

“Fly ash” is derived when coal is burned for energy and is produced in larger amounts than any other single industrial waste. In 1998, approximately 60 million metric tons of fly ash as well as 20 million tons of “bottom ash” and “boiler slag” materials and 25 millions metric tons of “flue gas desulfurization” by-products were produced in United States. All of the above-named materials are derived when coal is burned and are, in their conglomerate, referred to as coal combustion by-products. Fly ash is a fine (typically less than 0.05 mm in diameter) largely siliceous material derived from coal. It is removed from the flue gases by special collectors and about 25% is recycled as a cement additive, structural fill, or for other purposes. Fly ashes are classified as Class C or Class F and the properties of each type of fly ash are primarily because of the coal source and furnace operating conditions. Class C fly ashes are higher in alkali metals and Class F ashes have high silicon and Al contents. Bottom ashes are sand-like granular substances, which are typically used as aggregate in cement blocks, for construction backfill, and for treatment of snow or icy roads. Boiler slag is coarse textured and shiny black in appearance and resembles crushed glass. Its major applications include use as blasting grit, aggregate, granules for roofing shingles asphalt, and snow and ice abrasive. Flue gas desulfurization (FGD) by-products are created as a result of the Clean Air Acts, which mandate removal (or scrubbing) of sulfur from the flue gases when coal is burned. They are often a mixture of coal ash, gypsum, and unreactive lime, although the composition can vary tremendously based on the type of technology used to scrub the sulfur. FGD gypsum has become a major high-volume industrial by-product.

Pulp and Paper Manufacture

The production of pulp for papermaking and as an industrial feedstock by the Kraft and related processes is the major industry in several regions of United States. The total production of pulp and paper-manufacture materials in 1989 was approximately 13 million metric tons. Material properties are highly variable because of the wide range of processes used in wood digestion and in handling of the resultant wastes.

Construction Wastes

A large amount of construction waste is generated each year in the United States waste wallboard, lumber, waste fill material, and other construction materials. For example, in home construction, approximately 0.5 kg of wallboard waste is generated per square foot of floor space resulting in the annual production of about 1 million metric tons of waste. Typical construction waste of a 2000 ft² home is estimated to be 3600 kg.^[3]

LAND APPLICATION OF INDUSTRIAL BY-PRODUCTS

The physical form of industrial wastes can vary greatly, ranging from liquid to fine powders to large-sized pieces of construction wastes. Not all industrial wastes are destined to be entombed in landfills. Many have properties that make them beneficial as raw materials for subsequent manufactured products.^[4] For example, coal combustion by-products are commonly included in the preparation of high quality, high strength concrete. When industrial wastes are used in such a manner, they are really no longer considered wastes, but are valued as raw materials to create another type of industrial activity.

Many industrial wastes also have properties that make them valuable as soil amendments.^[4] Organic by-products from some food processing plants, e.g., when applied to

Table 2 Properties of soil that can be either improved or degraded by the application of by-products to soil.

Soil properties affected	Reasons these properties are important
Soil physical properties	Indicators of retention and transport of water and chemicals, soil erosion, leaching, surface and subsurface water runoff, and soil productivity
Texture	
Topsoil depth	
Rooting zone depth	
Water infiltration rate	
Soil bulk density	
Water-holding capacity	
Erodibility	
Compaction	
Soil chemical properties	Defines the fertility of the soil and the potential to either positively or negatively affect the soil's quality and the quality of the air and water that interact with the soil
Soil organic matter concentration	
pH	
Electrical conductivity	
Available plant nutrients	
Available heavy metals	Indicates the soil's microbial ability to degrade organic compounds in soil and the soil's potential to cycle nutrients and to purify the soil and water. The more microbial diversity maintained in an ecosystem, the better the ecosystem's ability to adjust to changes
Sorption capacity	
Soil biological properties	
Microbial biomass size	
Microbial biomass activity (i.e., respiration)	
Microbial diversity	
Redox potential	
Ability to biodegrade organic materials	

Note: All of the properties listed in the table are useful in models that seek to integrate soil, landscape, and geographic variability for the purpose of assessing and predicting impacts of applying by-products to soil.

Source: Adapted from Sims & Pierzynski.^[5]

soil can affect a large number of properties and lead to an increase in soil quality. A summary of the more important physical, chemical, and biological properties that can be affected by land application of by-products is provided in Table 2.

A large number of studies have been conducted to determine the best management practices for use of by-products as a soil amendment. This includes information such as that presented in Table 2 and also involves methods of application and techniques related to the application process itself.

ROLE OF REGULATORY AGENCIES REGARDING DISPOSAL AND REUSE OF INDUSTRIAL WASTES

Many states require that a plan be submitted to the state regulatory agencies, which provides information on the type of material to be land applied, the properties of the material, the rates to be applied, and how the material will be transported and applied. The by-product must be applied without creating odors, must often be mixed into the soil with farm machinery to reduce risk of runoff if a heavy rain should occur soon after application, and often cannot be applied within certain distances from wells, streams, houses, or other more sensitive areas. This is not to imply that all industrial by-products are toxic. Like medicines,

properly handled by-products can also be beneficial. Guidelines are established, however, to ensure good stewardship of our soil–water–air resources. Many states have guidelines for land application of by-products posted on the Internet.

The Resources Conservation and Recovery Act (RCRA), enacted on October 21, 1976, regulates the most hazardous of industrial wastes “from cradle to the grave.” The statute requires EPA to establish minimum acceptable requirements for all aspects of hazardous wastes for generators and transporters as well as for treatment, storage, and disposal facilities. The regulatory framework established under Subtitle C of RCRA was designed to protect human health and the environment from the effects of improper management of hazardous waste. Determining what is hazardous waste is therefore a key activity because only those wastes that meet the definition of hazardous waste are subject to Subtitle C. This is also a complex issue. In general, a material is classified as hazardous if it exhibits one of the EPA-defined characteristics of a hazardous waste (i.e., corrosive, ignitable, reactive, and toxic). A hazardous waste, however, must also meet the definition of a solid waste, and a solid waste is “any discarded material that is not specifically excluded” from a listing of solid wastes. Materials excluded by the various definitions of wastes are listed in Table 3.

Solid waste does not refer to the material’s physical state per se as it is a regulatory term only. Non-hazardous wastes,

Table 3 Exclusions from Subtitle C of RCRA.

Excluded from solid waste definition	Excluded from hazardous waste definition	Excluded materials requiring special management
Domestic sewage	Household wastes	Product storage wastes
Mixtures of domestic sewage and wastes going to publicly owned treatment works	Agricultural wastes used as fertilizers	Waste identification samples
Industrial point source discharges under Section 402CWA	Mining overburden returned to site	Treatability samples
Irrigation return flows	Discarded wood treated with arsenic	Residues remaining in empty containers
Source, special nuclear, or by-product material under AED	Specific ore and mineral beneficiating wastes	Conditionally exempt small-quantity generator wastes
		Farm wastes (pesticides)
<i>In situ</i> mining waste	Fossil fuel combustion wastes	PCB-mixed wastes ^a
Reclaimed pulling liquors from Kraft paper process	Oil and gas exploration, development and production wastes	Low-level radioactive mixed waste ^a
Spent sulfuric acid used to produce new acid	Cement kiln dust	
Secondary materials returned to the original process under certain conditions	Petroleum-contaminated media and debris from underground tank cleanup	
Spent reused wood preservatives	Spent chlorofluorocarbon refrigerant	
Certain coke by-products	Used oil filters	
Splash condenser dross residue	Still bottoms from the re-refining of used oil	
Recovered refinery oil wastes		

^aThese wastes are not explicitly excluded from RCRA but require special management.

Source: Adapted from Wagner.^[6]

as defined by RCRA, are not necessarily guaranteed to be safe for dispersal into the environment. Potential hazards could include soil degradation, surface and groundwater contamination, direct exposure during handling, or indirect exposure such as plant uptake into the food chain can all result in harmful environmental and human health effects.

MINIMIZING PRODUCTION OF INDUSTRIAL WASTES

In the late 1980s, many groups argued for a defined approach to the prevention of wastes (including industrial wastes). These efforts translated into the Pollution Prevention Act of 1990 and development of a qualitative hierarchy as a means to evaluate various approaches to pollution reduction in terms of their adherence to a pollution provision theme. A simple version of this hierarchy (from most to least desirable) is as follows: 1) source reduction, i.e., use of cleaner feed materials and processes; 2) reuse and recycle, especially in-process recycling; 3) treatment; and 4) disposal.^[7]

The Chemical Manufacturers Association^[8] has developed a five-step approach, which is applicable to the design and analysis of chemical manufacturing plants and can be used in various stages of design. This approach can be extended to many different industries that generate waste:

1. Step 1: characterize process streams.
2. Step 2: evaluate environmental impacts and issues.
3. Step 3: identify pollution prevention opportunities.
4. Step 4: analyze alternatives.
5. Step 5: document results.

CONCLUSION

Increasing human population and expanded industrial activities make it imperative that we pay attention to the

creation, recycling, and disposal of industrial wastes. Our quality of life will largely depend on how we address this issue. While progress has been made, there is a long way to go before we will achieve a truly sustainable way of life.

Abstract

Water infiltration rate is an important soil property with a strong impact on the environment. Factors such as field traffic, crop rotation, tillage operations, and fertilizer management affect water infiltration rate into the soil. Farmers need to be advised and encouraged to keep the infiltration capacity of their soils as high as possible by all means of agricultural measures.

INTRODUCTION

Infiltration rate is the velocity at which water enters into the soil. It is usually measured by the height (mm) of a water column that can penetrate the soil in 1 hour. There is a difference between 1) the initial infiltration rate, which reflects the rapid entry of water into dry soil; and 2) the equilibrium infiltration rate, which reflects the water infiltration into the soil at steady-state conditions.

High water infiltration rate or infiltration capacity of soil is an important precondition to reduce the risk of water erosion, to replenish water storage capacity, and to diminish the risk of temporal flooding of soil during extraordinary precipitation events.^[1] Soil surface sealing, soil compaction, loss of biological activity, and decrease in soil organic matter content have unfavorable impact on infiltration rates.

SOIL SURFACE DEGRADATION

Soil sealing and crusting are caused by the energy of raindrops during precipitation events. Surface seals are thin crusts ranging from a fraction of a millimeter up to several centimeters. In comparison with intact soil, the surface seal is characterized by higher bulk density along with higher shear and penetrometer resistances, low hydraulic conductivity, and reduced gas exchange processes.^[2] Sealed soils have markedly restricted infiltration

capacities,^[3] e.g., a 40–60% decrease in tilled bare systems. Surface crusting can be minimized by using mulches.^[4]

LAND USE AND FERTILIZATION

Maintaining high infiltration capacity of soil is one of the most significant achievements of agriculture and is used as a soil quality indicator. Infiltration rate and soil organic matter content are primarily functions of the prevailing land use system and the duration of cultivation (Fig. 1).^[5,6]

Conversion of natural into arable ecosystem affects the fate of stored carbon and associated properties such as bulk density, soil structure, and water infiltration rate. Soil degradation is exacerbated when perennial crops are replaced by annual row crops because of increased soil stress and disturbance of soil structure by tillage. In addition, intense rainfall may induce soil crusting, reduce macroporosity, and increase hard setting upon drying. Ley farming, a system of growing forages in rotation with agricultural crops for improving soil quality and sustaining grain and fodder production, is a viable alternative to enhance infiltration capacity.^[7]

Adopting complex crop rotations contributes to soil carbon sequestration and reduces dry bulk density through increased inputs of plant residues, longer periods of soil coverage, and less soil disturbance, resulting in enhanced infiltration rates (Fig. 2).^[6,8]

Fig. 1 Effect of management and soil properties on infiltration rates (measurement: summer 2003 with double ring infiltrometer in Germany and Romania; 100% = 332 mm/hr; fym: farm yard manure).

BASE SATURATION

Base saturation with Ca^{2+} and Mg^{2+} is an important factor influencing the stability of soil aggregates, so liming is a key measure in agriculture for the protection of soil structure. Nevertheless, a global decline of calcium balance in cultivated soils is widely observed. Liming requirement (adequate supply of Ca^{2+} and Mg^{2+} to balance leaching losses) is estimated indirectly from soil pH. However, other cations (NH_4^+ and K^+) affect soil structure and infiltration adversely (e.g., as a result of excessive liquid manure application). Soil pH alone cannot be used to adequately assess

the liming requirements to compensate for these effects. Research is urgently needed to accurately assess the lime requirement of soils.^[5]

DEGRADATION BY SALINIZATION

Soil salinization degrades soil structure, predominantly because of the replacement of Ca^{2+} and Mg^{2+} by Na^+ , resulting in decreased infiltration, increased surface hardness, and erosion by both rainfall and overland flow. Regeneration processes to increase the water infiltration

Fig. 2 Crop rotation, dry bulk density, and infiltration rate for different farming systems (measurement: spring 2004 with hood infiltrometer on the Trenthorst site, Germany; 100% = 179 mm/hr).

Source: From Schnug, Rogasik et al.^[8]

in saline soils can be initiated using gypsum together with deep ripping.^[9] Applying xenobiotic substances (e.g., acrylamides) to soils or with irrigation water can initiate the restorative processes^[10] but only when used in conjunction with gypsum.

SOIL TILLAGE SYSTEMS

Tillage methods significantly affect the soil's physical properties. Conversion from conventional to conservation tillage reduces soil disturbance and enhances soil resistance to compaction by vehicular traffic. Additionally, earthworm activity is improved by greater sources of food and undisturbed burrows.^[11,12] Earthworms create stable vertically oriented macropores with high continuity and connectivity,^[13,14] which are preferential water flow paths and thus increase infiltration rates.^[15]

Intensive soil tillage disrupts fauna and soil aggregates followed by the loss of mechanical stability, reduction in infiltration capacity, and increase in susceptibility against competitive forces (Fig. 3).

Reduced tillage intensity and the maintenance of residue cover ensure high soil structural stability and diminish surface sealing, preventing the formation of plow or traffic pans and increasing water infiltration capacity.^[17]

TRAMPLING

Changes in soil structure from cattle or sheep hoof compaction can cause severe problems of soil degradation on rangelands. Inappropriate grazing management (high stocking rates and continuous grazing) can increase the dry bulk density and tensile strength and decrease water

infiltration rates because of a reduction in macroporosity. Regeneration of soils requires the adoption of low stocking rates,^[18] controlled grazing, and no grazing during periods of high soil moisture contents, which is especially important under irrigated conditions.^[19]

SUBSOIL COMPACTION CONTROL

Plant roots, especially those of perennial species (e.g., alfalfa), can ameliorate compacted subsoil through bioturbation. Furthermore, growing cover crops can also improve soil structure.^[7] The prevention of field traffic-induced subsoil compaction includes management to enhance soil stability (reducing depth of tillage, minimum tillage, direct drilling, and minimizing soil loosening), regenerate soil structure (green manuring, providing continuous vegetal cover, supplying sufficient organic matter, and growing deep-rooted cover crops), avoid subsoil compaction by reducing in-furrow plowing, use appropriate machinery with limited wheel or axle loads, change to running gear with restricted ground contact pressures, and ensure controlled traffic.^[20]

CONCLUSION

Water infiltration rate is an important soil property with a strong impact on the environment. Factors such as field traffic, crop rotation, tillage operations, and fertilizer management (lime status and soil organic carbon) affect water infiltration rate into the soil. Farmers need to be advised and encouraged to keep the infiltration capacity of their soils as high as possible by all means of agricultural measures.

Abstract

This entry reviews infiltration and standard modeling strategies. Models to characterize the infiltration for field applications usually employ simplified concepts, which predict the infiltration rate or cumulative infiltration volume and assume that surface ponding begins when the surface application rate exceeds the soil surface infiltration rate.

INTRODUCTION

Infiltration is commonly defined as the process of water entry at the land surface into a soil from a source such as rainfall, irrigation, or snowmelt. The rate of infiltration is generally controlled by the rate of soil water movement below the surface. Factors that affect infiltration have been divided into categories of soil, surface, management, and natural properties.^[1] These factors should be taken into account in the infiltration model parameters. Soil factors encompass soil particle size and morphological, chemical, and soil water properties.^[2] Surface factors are those that affect the movement of water through the air–soil interface such as soil crust. Management systems involve different types of tillage, vegetation, and surface cover.^[2,3] Natural factors include such things as precipitation, soil temperature, residue, and soil moisture, which vary with time and space, and interact with other factors in their effect on infiltration.

INFILTRATION MODELS

Models to characterize infiltration for field applications usually employ simplified concepts, which predict the infiltration rate or cumulative infiltration volume and assume that surface ponding begins when the surface application rate exceeds the soil surface infiltration rate. The evolution of infiltration modeling has taken three directions: the empirical, the approximation to the physically based models, and the physically based approach. Most of the empirical and approximate models treat the soil as a semi-infinite medium with the soil saturating from the surface down. Physically based models specify appropriate boundary conditions and normally require detailed data input. The Richards equation is the physically based infiltration equation primarily used for describing water flow in soils; however, it has not been used in operational infiltration models.

The empirical models generally relate infiltration rate or volume to elapsed time modified by certain soil properties.^[4] Parameters used in these models are commonly estimated from measured infiltration rate–time relationships for a given soil condition. The three most common empirical models were proposed by Kostiakov,^[5] Horton,^[6] and Holtan.^[7] The most common physically based models were proposed by Green and Ampt,^[8] Phillip,^[9] Morel-Seytoux and Khanji,^[10] and Smith and Parlange.^[11]

MODEL PARAMETERS

The most common ways to determine infiltration parameters are to fit models to experimental infiltration data (infiltration rate as it varies with time) or to develop relationships between readily available data such as soils and land use data and the infiltration model parameters.

Experimental infiltration measurements are normally made by applying water at a specific site to a finite area and measuring the intake rate of the soil. There are four types of infiltrometers, namely: the *ponded water ring* or *cylinder* type, the *sprinkler* type, the *tension* type, and the *furrow* type. When choosing an infiltrometer, one must choose the one that replicates the system being investigated. For example, ring infiltrometers should be used to determine infiltration rates for inundated soils such as flood irrigation or pond seepage. Sprinkler infiltrometers should be used where the effect of rainfall on surface conditions influences the infiltration rate. Tension infiltrometers are used to determine the infiltration rates of the soil matrix in the presence of macropores. Furrow infiltrometers are used when the effect of flowing water is important such as furrow irrigation.^[12]

The Green–Ampt^[8] model is typical of physically based models and has probably had the most effort directed toward estimating the parameters from readily available data. Also, as shown in [Table 1](#), the Green–Ampt parameters can

Table 1 Physically based infiltration capacity models, assuming immediate ponding.

Source: From Rawls & Brakensiek.^[13]

be used to estimate the parameters for most of the physically based models.^[13]

The Green–Ampt^[8] model is an approximate model utilizing Darcy’s law. The original model was developed for ponded infiltration into a deep homogenous soil with a uniform initial water content. Water is assumed to infiltrate into the soil as piston flow resulting in a sharply defined wetting front that separates the wetted and unwetted zones. When neglecting the depth of ponding at the surface, the Green–Ampt rate equation is as follows

$$f = K(1 + (\phi - \theta_i)H_f/F) \quad (1)$$

where K is the effective hydraulic conductivity (cm/h), H_f is the effective suction at the wetting front (cm), ϕ is the soil porosity (cm³/cm³), θ_i is the initial water

content (cm³/cm³), F is accumulated infiltration (cm), and f is the infiltration rate (cm/h).

The Green–Ampt parameters can be estimated from the readily available data such as soils and land use data,^[14] e.g., average values for the Green–Ampt wetting front suction, S_f ; saturated hydraulic conductivity, K_s ; and porosity, ϕ , are given in Table 2 for the 11 U.S. Department of Agriculture soil textures. These values can be used as a first estimate; however, if more detailed soil properties are available, more refined estimates can be made.

Porosity

Table 2 gives the estimates of porosity for soil textures; however, the porosity, ϕ , can be estimated from measured

Table 2 Green–Ampt parameters.

Soil texture class	Porosity, ϕ	Wetting front soil suction head, S_f	Saturated hydraulic conductivity, K_s
Sand	0.437 (0.374–0.500)	4.95 (0.97–25.36)	23.56
Loamy sand	0.437 (0.363–0.506)	6.13 (1.35–27.94)	5.98
Sandy loam	0.453 (0.351–0.555)	11.01 (2.67–45.47)	2.18
Loam	0.463 (0.375–0.551)	8.89 (1.33–59.38)	1.32
Silt loam	0.501 (0.420–0.582)	16.68 (2.92–95.39)	0.68
Sandy clay loam	0.398 (0.332–0.464)	21.85 (4.42–108.0)	0.30
Clay loam	0.464 (0.409–0.519)	20.88 (4.79–91.10)	0.20
Silty clay loam	0.471 (0.418–0.524)	27.30 (5.67–131.50)	0.20
Sandy clay	0.430 (0.370–0.490)	23.90 (4.08–140.2)	0.12
Silty clay	0.479 (0.425–0.533)	29.22 (6.13–139.4)	0.10
Clay	0.475 (0.427–0.523)	31.63 (6.39–156.5)	0.06

Note: Numbers in parentheses are the 25% and 75% ranges.

Source: Adapted from Rawls, Brakensiek, et al.^[15]

bulk density or from soil particle size data (% sand and % clay), % organic matter, and cation-exchange capacity of the clay (an indicator of the shrink–swell capacity of the clay).^[16] Coarse fragments (>2 mm in size) in the soil affect the porosity, and adjustments should be made.^[17]

Initial Water Content

The initial water content (θ_i) should be measured, or it can be estimated from moisture–retention relationships.^[14] Good estimates of wet, average, and dry initial water contents are the water content held at –10, –33, and –1500 kPa, respectively.

Wetting Front Suction

The Green–Ampt wetting front suction parameter (H_f) can be estimated from the parameters of the Brooks–Corey water retention equation:^[14]

$$H_f = ((2 + 3\lambda)/(1 + 3\lambda))(h_b/2) \quad (2)$$

where H_f is the Green–Ampt wetting front suction (cm), λ is the Brooks–Corey pore size distribution index, and h_b is the Brooks–Corey bubbling pressure.

Rawls and Brakensiek further simplified the above equation by relating the Green–Ampt wetting front suction parameter to soil properties in the following equation:

$$\begin{aligned} H_f = & \exp[6.53 - 7.326(\phi) + 0.00158(C^2) \\ & + 3.809(\phi^2) + 0.000344(S)(C) \\ & - 0.04989(S)(\phi) + 0.0016(S^2)(\phi^2) \\ & + 0.0016(C^2)(\phi^2) - 0.0000136(S^2)(C) \\ & - 0.00348(C^2)(\phi) - 0.000799(S^2)(\phi)] \end{aligned} \quad (3)$$

where S is the % sand, C is the % clay, and ϕ is the porosity (vol.%).

Effective Hydraulic Conductivity

The effective hydraulic conductivity can be obtained from measurements or from saturated hydraulic conductivity prediction techniques developed from physical and hydraulic soil properties and modified for management and natural conditions. If only soil texture classes are available, the saturated hydraulic conductivity can be obtained from Table 2 and, as a rule of thumb, the effective hydraulic conductivity can be taken as half of the saturated hydraulic conductivity. There are various techniques for estimating saturated hydraulic conductivity from soil properties^[18,19] or characteristics of the water retention curve.^[15,20,21] Other techniques are given in the hydraulic conductivity section.

The effective hydraulic conductivity is determined by modifying the saturated hydraulic conductivity to incorporate the effects of such factors as coarse

fragments (>2 mm in size),^[17] soil freezing,^[14] soil crusts,^[22] and macropores.^[23]

A practical approach to handling the various conditions is to set the effective hydraulic conductivity equal to the saturated hydraulic conductivity (K_s) times a macroporosity factor.^[12] Brakensiek and Rawls^[1] developed two macroporosity factors for areas that do not undergo mechanical disturbance on a regular basis (e.g., rangeland) and one for areas that do (e.g., agricultural areas). For the bare area outside a plant canopy, the soil is assumed to be crusted, and the effective hydraulic conductivity is equal to the saturated hydraulic conductivity (K_s) times a crust factor.

CONCLUSION

Defining infiltration parameters that represent the conditions at a point are well established; however, defining how these parameters vary both temporally and spatially has only been defined in a very elementary way, and an elaborate research is needed in these areas.

Inorganic Carbon: Analysis

Richard R. Drees

C. Tom Hallmark

Department of Soil and Crop Sciences, Texas A&M University, College Station, Texas, U.S.A.

Abstract

Numerous methods for determining soil inorganic carbon exist. The nature of the soil investigation and the intended use of carbonate data govern the technique of choice. This entry presents techniques that are simple and accurate, requiring commonly available laboratory apparatus and reagents.

INTRODUCTION

Soil inorganic carbon (SIC) exists primarily as carbonates of calcium [Ca; e.g., calcite (CaCO_3)] and calcium plus magnesium [Mg; e.g., dolomite ($\text{CaMg}(\text{CO}_3)_2$)]. Carbonates may be pedogenic (i.e., formed in the soil) or lithogenic (i.e., inherited from calcareous parent materials). CaCO_3 is dominant in pedogenic environments, although $\text{CaMg}(\text{CO}_3)_2$ has been reported to occur under certain conditions.^[1] Many animal shells are also calcareous—often aragonite, which is another form of CaCO_3 . Other unique carbonate minerals may exist in soil, but regional geologic settings or unique environmental conditions govern their existence.

Soil is a major reservoir of inorganic carbon, containing more carbon than the atmosphere and biosphere combined.^[2] The estimates of SIC are important in evaluating carbon reserves, rates of carbon sequestration, or loss from the soil system. Also, the presence of carbonates has a major influence on soil chemical and physical reactions.

There are numerous procedures for SIC determination, and many excellent reviews exist.^[3–6] Each technique uses unique physical, chemical, or mineralogical properties of carbonates. It is not our intent to repeat the details of these procedures, but rather to present the fundamental basis of analysis and to focus on commonly used procedures in soil investigations.

CHEMICAL REACTIONS

Carbonates dissolve in strong acids. Ideal reaction equations are:

or

These reactions can be used to determine carbonates by measuring the weight loss due to carbonate dissolution, amount of carbon dioxide (CO_2) produced, or the amount of acid consumed in the reaction. The reaction rate of calcite 1 is much greater than $\text{CaMg}(\text{CO}_3)_2$ (Eq. 2) when particle size and surface area are standardized,^[6] which permits quantitative determination of the two minerals. For techniques that cannot differentiate CaCO_3 from $\text{CaMg}(\text{CO}_3)_2$, results are reported as CaCO_3 equivalent.

Gravimetric Techniques

The reaction of carbonates with a strong acid releases CO_2 , resulting in a weight loss (Eqs. 1 and 2). The weight loss is a direct measure of carbonates.^[3,5]

$$\% \text{CaCO}_3 \text{ equivalent} = \frac{\text{g CO}_2 \text{ lost}}{\text{g oven-dried soil}} \times 227.3 \quad (3)$$

Weight gained by trapping evolved CO_2 gas with an absorbent is another common technique for carbonate determination.^[6] There are two methods of generating CO_2 for gravimetric techniques: 1) treating carbonates with acid (Eqs. 1 and 2) and 2) heating the sample (dry combustion) to 1000°C after organic carbon removal to release carbonate CO_2 ^[7] in the reaction:

In both instances, evolved CO_2 is passed through a series of traps to absorb water and other reaction constituents before the gas passes through a Nesbitt absorption bulb containing sodium hydroxide (NaOH) to absorb CO_2 and Mg perchlorate to retain the water generated in the reaction.^[6]

The calculations are the same as in Eq. 3, except that weight gain replaces weight loss. For the acid reaction, if the weight gain/loss is monitored over time, $\text{CaMg}(\text{CO}_3)_2$

content can be determined due to its slower reaction rate. However, it is not possible to differentiate CaCO_3 and $\text{CaMg}(\text{CO}_3)_2$ by the dry combustion method.^[7]

Volume/Pressure Techniques

Measurements of gas evolution are relatively rapid and are often used to determine soil carbonates. The common techniques used are a volumetric measure of evolved CO_2 (constant pressure) and an increase in pressure (constant volume). For the constant pressure procedure (commonly called the Chittick procedure), soil is treated with a strong acid, and the volume of released CO_2 is directly correlated with carbonate content.^[6,8] Fig. 1 illustrates a constant pressure apparatus. A finely ground sample is weighed to the nearest 0.1 mg and placed into a decomposition flask. By a stopcock (S in Fig. 1), the reaction vessel is closed to the atmosphere just before introducing the acid.

The leveling bulb and burette contain a saturated salt solution with a red indicator dye for easy reading.^[3] As the acid is added, the sample is stirred to provide a uniform

reaction, and the leveling bulb is constantly adjusted to maintain a slight negative pressure. After carbonates have reacted, the volume of solution displaced is measured. Timing of the reaction is important because CaCO_3 and $\text{CaMg}(\text{CO}_3)_2$ have different reaction rates. The volume change after 30 seconds is often used as a measure of CaCO_3 , and any volume increase between 30 seconds and 2 hours is attributed to $\text{CaMg}(\text{CO}_3)_2$. Adjustments are made for changes in temperature and atmospheric pressure during the reaction. Calculations to convert gas volume to weight percentage carbonates are given by several authors.^[5,6]

When carbonates react with acid at constant temperature and volume, the gas released causes an increase in gas pressure that is directly related to carbonate content.^[9–13] A pressure gauge, pressure transducer, or manometer is used to monitor the change in pressure over time. Pressure transducers can be connected to a personal computer for instantaneous data acquisition. Pressure change over time can be used to quantify CaCO_3 and $\text{CaMg}(\text{CO}_3)_2$ and has been shown to be highly sensitive and rapid.^[13]

The change of volume or pressure with CO_2 evolution has certain limitations. The solubility of CO_2 in acid varies with temperature, the type of acid used, acid concentration, and barometric pressure.^[3,6] Calibration with pure CaCO_3 and $\text{CaMg}(\text{CO}_3)_2$ standards is required in both the constant pressure and constant volume system for accurate results.

Titrimetric Techniques

Carbonates are the only major soil constituents that readily react with acids. The amount of acid consumed (Eqs. 1 and 2) during reaction with carbonates can be determined by titrating the unreacted acid to a common end point with a base. Normally, 50 ml of standardized 0.5 N HCl is carefully introduced to 5–25 g of soil, and the soil acid mixture is gently boiled for 5 minutes and then allowed to cool. The suspension is filtered and washed to remove all acid. The filtrate is then titrated with standardized 0.25 N NaOH to the phenolphthalein end point^[3,14] to determine the amount of acid consumed:

% CaCO_3 equivalent

$$= 100 \times \frac{(\text{Meq HCl added} - \text{Meq NaOH used})}{\text{g oven-dried soil}} \times 0.05 \text{ g CaCO}_3/\text{Meq} \quad (6)$$

X-RAY DIFFRACTION

Carbonates are crystalline minerals that yield characteristic X-ray diffraction peaks. The intensity of the diffraction peak should be proportional to the quantity of carbonate present. Accuracy is dependent on carbonate crystallinity, particle size, chemical composition, and sample orientation.^[15] Excellent results can be attained

Fig. 1 Constant pressure apparatus for carbonate determination. Source: From Dreimanis.^[8]

using mineral standards [CaCO_3 or $\text{CaMg}(\text{CO}_3)_2$] and an internal reference standard.^[16] A calibration curve is constructed that plots the internal standard/mineral standard intensity ratio against the weight percentage of the mineral standard.^[16] In most instances, carbonate-containing samples and reference standards must be ground to produce a uniform, small particle size. Increased grinding time generally yields a decrease in error.^[17]

X-ray diffraction has proved to be a reliable semiquantitative method for the determination of $\text{CaMg}(\text{CO}_3)_2$ in carbonate rocks and sediments even without an internal standard.^[18] Peak intensities corrected for absorption also achieved accurate results in carbonate rocks,^[19] but it is unclear how this method would work for samples of low carbonate concentration. Due to slight differences in diffraction intensity between carbonates, it is recommended that reference carbonates be as similar as possible to those contained in the soil being analyzed.^[15]

Mg may substitute for Ca within the CaCO_3 structure up to approximately 10 mole%. X-ray diffraction can differentiate pure CaCO_3 from Mg-substituted CaCO_3 , whereas other techniques cannot. Small amounts of Mg substituted within the CaCO_3 structure result in slight shifts in diffraction peaks that have been calibrated with the amount of Mg substitution.^[20]

THIN SECTIONS

Carbonate minerals can usually be readily identified in thin sections by the high birefringence of carbonates and the microstructure of shells. Thin section techniques are time-consuming because sample preparation is lengthy and quantification relies on point count determinations,^[21] which are laborious. Accuracy depends on carbonate quantity, distribution, particle size, and how well the section is representative of the sample as a whole. As particle size decreases, positive identification becomes more difficult^[17] with a lower practical limit of detection of approximately 20 μm . For low concentrations (<10%), quantification becomes problematic. Despite limitations, microscopic examinations of soil material may differentiate pedogenic from lithogenic carbonates,^[22] which can have implications in soil genesis studies.

CaCO_3 and $\text{CaMg}(\text{CO}_3)_2$ often look similar in thin sections. $\text{CaMg}(\text{CO}_3)_2$ typically has rhombohedral habits, but this cannot be relied upon as a differentiating criterion. Chemical staining techniques have been used successfully to differentiate carbonate species.^[15,17,23–25]

X-RAY FLUORESCENCE AND MICROPROBE

X-ray fluorescence determines the chemical composition of a bulk sample, whereas microprobe is more site specific. Interpretation is based on assigning chemical composition to specific minerals. There are limitations in this

assignment, since other minerals contain Ca and Mg, and carbon approaches the detection limit of many instruments. In microprobe analyses, common stoichiometric correction factors may result in errors up to 20%.^[26] These are probably not the best techniques for carbonate determination, especially in low concentrations, for they are indirect and do not employ characteristic properties of carbonate minerals. However, if carbonate concentrations are above 10–20% and other analyses indicate that there are none to few other Ca- or Mg-bearing minerals, X-ray fluorescence and microprobe analysis of total Ca and/or Mg may be good indicators of carbonates.

Microprobe analysis is particularly useful in determining Ca/Mg ratios in $\text{CaMg}(\text{CO}_3)_2$ or Mg-substituted CaCO_3 of individual crystals, as it is site specific. However, it is not as efficient in bulk sample analysis as other techniques relying on carbonate reaction.

CONCLUSION

Numerous methods for determining SIC exist. The nature of the soil investigation and the intended use of carbonate data govern the technique of choice. Although highly sophisticated instruments can be used, the simple titrimetric technique (Eq. 6) and the change in gas volume or pressure upon reacting carbonates with acid (Fig. 1) are popular. Such techniques are simple and accurate, requiring commonly available laboratory apparatus and reagents. The change in gas pressure or volume has the advantage of differentiating between CaCO_3 and $\text{CaMg}(\text{CO}_3)_2$. The change in gas pressure technique may gain some favor because a pressure transducer can be connected to a personal computer for instantaneous results.

Inorganic Carbon: Climate and Time

Lee C. Nordt

Department of Geology, Baylor University, Waco, Texas, U.S.A.

Abstract

Knowing the formation and distribution of soil inorganic carbon (SIC) components is important for the mapping and classification of soils, understanding carbonate equilibria reactions, better interpreting of the role of soils in the global carbon cycle, and understanding feedback mechanisms that soil may provide in a greenhouse world.

INTRODUCTION

Soil inorganic carbon (SIC) is contained in solid, solution, and gaseous phases with the regional and global distribution dependent, in large part, on the influence of climate and time.^[1] Common sources for the solid SIC phase are limestone (calcite and dolomite), carbonate-rich airborne dust, and unconsolidated calcareous parent materials such as alluvium, loess, and till. The gaseous phase consists of soil-respired carbon dioxide (CO_2) that is generated by plant and animal respiration and by the influx of atmospheric CO_2 into the upper part of the soil profile. The CO_2 phase combines with water to produce a solution enriched in carbonic acid (H_2CO_3) and bicarbonate (HCO_3^-). H_2CO_3 also enhances weathering of calcareous parent materials and calcium-bearing silicates that generates Ca^{2+} and CO_3^{2-} [or $\text{Ca}(\text{HCO}_3^-)_2$] by-products in the solution phase. Dissolution is enhanced in the upper soil profile where there is a greater flux of water, higher CO_2 production from respiration, and a lower pH.

The recombination of ions from solution into a solid SIC phase leads to the formation of pedogenic carbonate. Formation typically occurs below the zone of maximum biological activity where CO_2 production is lower and pH is higher. Further, because of evapotranspiration and drying at the terminus of the wetting front, the ionic concentration of Ca^{2+} and CO_3^{2-} may exceed the solubility product of calcium carbonate (CaCO_3). In association with a shallow groundwater table, capillary rise in soils can also contribute to the concentration of Ca^{2+} and CO_3^{2-} ions and, ultimately, to the formation of pedogenic carbonate. Also, the role of microorganisms and roots in the formation of CaCO_3 is recognized, but its importance and extent are largely unknown.^[2] Under well-drained conditions, and in soils with pHs greater than 6.5, CaCO_3 is the dominant SIC solid species.

When pedogenic forms of carbonate are visible in the field, the associated soil horizons are commonly

described as Bk (filaments, soft masses, nodules) or Bkm (indurated). Although not formally recognized, there is evidence that disseminated pedogenic carbonate accumulates in near-surface horizons not visible in the field.^[3]

SIC AND CLIMATE

The global distribution of soil CO_2 , HCO_3^- , and CaCO_3 is determined, in part, by climate, particularly in response to rainfall and temperature. The concentration of soil CO_2 is commonly 10 to 100 times greater than at the soil-atmosphere interface (365 ppmV) because of biotic respiration and organic matter decomposition.^[4] Soil CO_2 concentrations are greater in warm-humid climates where rainfall and respiration rates are higher and decrease systemically to hot- or cold-arid climates where rainfall and respiration rates are lower. Soil respiration rates and CO_2 concentrations typically increase with elevation in arid to semiarid regions in response to more rainfall, cooler temperatures, and less evapotranspiration.^[5] In areas where soil CO_2 concentrations are relatively low (arid), atmospheric CO_2 can penetrate into the soil to depths of as much as 50 cm.^[6] Increased greenhouse gases and global warming could in some areas increase soil respiration rates.^[7]

As CO_2 dissolves in soil water, the inorganic carbon species H_2CO_3 is formed, which rapidly dissociates to HCO_3^- in soils with pH above 6.5.^[8] The production of HCO_3^- will be greater in warm-humid climates, especially where there are high respiration rates or rapid weathering of carbonate-rich parent materials. The fate of HCO_3^- in leaching soils is typically to deep groundwater and to rivers.^[9] In arid to semiarid regions where evapotranspiration is high and rainfall is low, HCO_3^- may become part of the SIC pool as pedogenic carbonate. Elevated soil CO_2 levels generated in some areas by global warming could enhance HCO_3^- production from

increased interaction of water and CO_2 , leading to lower soil pH and more intense weathering of primary and other secondary minerals.^[7]

Retallack^[10] provided a robust data set quantifying the relationship between rainfall and depth to the top of Bk horizons in warm-temperate climates (Fig. 1). This relationship indicates that at less than 100 mm of mean annual precipitation, insufficient soil moisture is available for weathering and for the production of visible forms of pedogenic carbonate. In contrast, most soils are leached of carbonate within the upper 1.5–2 m when mean annual precipitation exceeds 1000 mm. Using a national soil taxonomic data base, the rainfall to depth of pedogenic carbonate relationship has been brought into question.^[11] Careful control is needed to ensure that climate is the primary soil-forming factor in using this relationship for paleoenvironmental reconstruction.

SIC AND TIME

In the initial stages of soil formation, the production and concentration of CO_2 likely increase over decades to centuries as pioneer plant communities evolve into climax plant communities. Soil CO_2 production may decrease with time in response to vegetation disturbances created by increased aridity, soil erosion, overgrazing, or plowing.^[7]

In general, soil HCO_3^- in solution will increase or decrease in proportion to the production of soil CO_2 . However, if continued weathering leads to greater concentration of H^+ , a more acidic soil environment may produce more H_2CO_3 at the expense of HCO_3^- . Another long-term

Fig. 1 Relationship between mean annual precipitation (P) in millimeters and depth to top of Bk horizon (D) in centimeters. The relationship is described by the equation $P = 139.6 - 6.388D - 0.01303D^2$, with a correlation coefficient of 0.79 and a standard error of ± 33 cm. Results derived from well-drained and loamy, calcareous soils in warm-temperate climates principally for Stages II and III carbonate morphologies.

Source: From Retallack.^[10]

mechanism for decreasing HCO_3^- in soil solution is related to the weathering and depletion of parent material carbonate.

Gile and colleagues^[12] proposed a model of carbonate formation recognized as morphological stages for desert climates. For the model, it is assumed that a sufficient supply of Ca^{2+} and HCO_3^- ions are provided to form all stages of carbonate development. In addition, minimal climatic change during the interval of pedogenesis is ideal. The rate at which carbonate development passes through the individual stages is also dependent on parent material texture.

With these caveats in mind, the carbonate stages are designated Stage I, II, III, and IV from least to most developed. In non-gravelly parent materials, it can take 25,000–75,000 years to progress from Stage I (filaments) to Stage III (weakly indurated mass) in the formation of Bk horizons (Fig. 2). Stage IV represents nearly complete plugging of macropores forming a laminar cap and Bkm horizon. In desert environments, this process can take as long as 400,000 years (Fig. 2).

Machette^[13] proposed two additional morphological stages reflecting the further passage of time and enhanced geomorphic activity. Stage V is also recognized as a Bkm horizon but with a laminar cap greater than 1 cm thick. Stage VI is characterized by multiple episodes of

Fig. 2 Morphological stages of pedogenic carbonate with time in non-gravelly parent materials of arid to semiarid regions of the Southwestern United States. Not shown are advanced carbonate morphologies typifying Stages V and VI.

Source: From Gile, Hawley, et al.^[12]

brecciation and recementation and is thought to have formed over a period of 2 million years.

Similar stages of carbonate development form in soils with gravelly parent materials.^[12] Stage I results from the accumulation of carbonate pendants on the bottom of gravels. Stage II forms with nearly complete encasement of the gravels with a coat of carbonate. The more advanced stages have similar morphologies to the carbonate that accumulates in non-gravelly parent materials. However, because of reduced inherent porosity, the first four stages can be attained within 25,000–50,000 years of soil formation.

In soils formed from indurated and soft limestone, the upper surface tends to undergo numerous *in situ* dissolution–precipitation cycles that generate limestone porosity, unique pedogenic carbonate morphological fabrics, and eventually a laminar cap. Rabenhorst and colleagues^[14] present a model showing five stages of carbonate development in this system for semiarid to subhumid climates. Initial stages involve the accumulation of pedogenic carbonate around macrovoids either weathered into limestone or along fracture planes. Advanced stages culminate in complete plugging of both macro- and micropores along with the formation of a laminar cap.

SIC: INTEGRATION OF CLIMATE AND TIME

As shown in Fig. 3, the morphological characteristics of soil carbonate generally reflect the combined effects of climate and time. In this idealized example, it is assumed

Fig. 3 Integrative effects of climate and time on horizonation and pedogenic carbonate development in soils formed from calcareous parent materials in well-drained, loamy soils.

Source: From Nordt, Wilding, et al.^[9]

that the soils are loamy, well drained, calcareous, and formed in warm-temperate climates. Horizontally, the effects of time on soil development for a constant climate can be observed. In contrast to arid to semiarid climates discussed previously, carbonate development may never pass through Stage I in humid climates before net leaching of carbonate by-products begins to intensify. Here, A-E-Bt horizon sequences quickly form at the expense of incipient Bk and Bw horizons. In transitional subhumid climates, Bk horizons may eventually evolve into Bt horizons in the upper profile with Bk horizons persisting at depth.

Observing Fig. 3 vertically across climatic regions while holding time constant provides another view of these complex relationships. At 1000 years, incipient Bk horizons form quickly in subhumid and humid climates. At the endpoint of weathering at >75,000 years, A-Bkm horizons may form and persist in arid to semiarid climates with well-developed A-E-Bt horizons forming in subhumid and humid climates.

CONCLUSION

Knowing the formation and distribution of SIC components is important for the mapping and classification of soils, understanding carbonate equilibria reactions, better interpreting of the role of soils in the global carbon cycle, and understanding feedback mechanisms that soil may provide in a greenhouse world.

Abstract

Understanding pedogenic carbonate formation has been extremely useful for understanding relative ages of geomorphic surfaces and landscape evolution. A knowledge of pedogenic carbonate formation has also been useful for soil classification. Studies of pedogenic carbonate have expanded to include questions about paleoclimate, paleoecology, paleoatmospheric composition, global carbon cycles, and the greenhouse effect.

INTRODUCTION

It has become increasingly common for “soil inorganic carbon” to mean soil carbonate mineral carbon, mainly calcium carbonate (CaCO_3). In the strict sense, however, inorganic carbon encompasses not only carbon in carbonate minerals but also carbon in the carbonic acid system.^[1] The carbonic acid system includes gaseous carbon dioxide [$\text{CO}_{2(g)}$], aqueous carbon dioxide [$\text{CO}_{2(aq)}$], carbonic acid ($\text{H}_2\text{CO}_{3(aq)}$), bicarbonate ion ($\text{HCO}_3(aq)^-$), and carbonate ion ($\text{CO}_3(aq)^{2-}$).

COMPOSITION

In the soil solution, as with other solutions, the interaction of these species can be represented by the following reaction:^[1]

Cations, such as Ca^{2+} , Mg^{2+} , Fe^{2+} , Mn^{2+} , and Na^+ , precipitate with HCO_3^- (which is the dominant anion between pH 6.5 and 10.5) and CO_3^{2-} (which is the dominant anion above pH 10.5) to form a variety of carbonate minerals. The reaction of $\text{Ca}_{(aq)}^{2+}$ with $\text{HCO}_3(aq)^-$ to form calcite is illustrated below:

There are about 60 carbonate minerals, which in addition to calcite, include aragonite (CaCO_3), dolomite

[$\text{CaMg}(\text{CO}_3)_2$], siderite (FeCO_3), magnesite (MgCO_3), rhodocrosite (MnCO_3), cerussite (PbCO_3), and malachite [$\text{CuCO}_3\text{Cu}(\text{OH})_2$]. In soil, the overwhelmingly abundant carbonate mineral is calcite.^[2] In unique soil environments, however, other carbonate minerals have been found, such as pedogenic siderite and dolomite.^[3]

Individual carbonate crystals of pedogenic origin are generally too small to be seen with the unaided eye. When concentrated together, their combined presence takes on a white color with a variety of macroscopic forms. These forms include carbonate filaments (also called mycelia, pseudomycelia, and threads), films, coatings, soft spheroidal segregations (white eyes), nodules, cylindroids, concretions, glaeboles, and veins. Soil fabric that is impregnated with carbonate to the point that it occurs as an essentially continuous medium has been termed “k-fabric.”^[4] Stages of morphogenetic carbonate accumulation, in which progressively greater amounts of carbonate occur in progressively older soils, are important chronologic indicators. The calcic and petrocalcic horizons are diagnostic horizons in Soil Taxonomy.^[5] Calcic horizons generally contain greater than 15% carbonate by weight. Petrocalcic horizons are indurated forms of calcic horizons. Examples of these horizons are shown in Figs. 1A and B. Examples of carbonate crystals as viewed with optical microscopy and scanning electron microscopy are shown in Figs. 1C and D.

The dissolution of carbonates in soil systems can be represented by the following reaction (Eq. 3). In humid regions, soluble products of this weathering reaction flux through the vadose zone into groundwater, or precipitate as pedogenic carbonates deep in the soil or geologic system. In arid regions, soluble products precipitate at relatively

Fig. 1 Examples of inorganic carbon as it exists in the field and under the microscope. The white horizon is a calcic horizon in (A) and petrocalcic horizon in (B). The small golden crystals in (C) are calcite crystals coating sand grains; the black region is a pore space as it appears in cross-polarized light. A calcified fungal filament viewed with scanning electron microscopy is shown in (D).

shallow depths as a result of sparse rainfall and insufficient leaching.

FORMATION

Being located in an arid, semiarid, or subhumid climate is the primary factor that controls carbonate formation. In many areas, the boundary between carbonate-accumulating soil and non-carbonate-accumulating soil is about 500 mm (20 in.) mean annual rainfall.^[6] This relationship is confounded, however, by the effects of soil temperature, soil drainage, nature and properties of the parent material (e.g., soil texture, carbonate content, carbonate mineralogy, and porosity), soil drainage, land-form position, geomorphic stability, and effectiveness of precipitation (rainfall intensity and duration). Hence, there are many examples in humid and subhumid environments

where soil carbonate persists in the soil system at depths inconsistent with regional models. In humid regions, for example, inorganic carbon persists as calcite or dolomite detritus in soils derived from certain parent materials (e.g., calcareous loess, till, outwash, alluvial deposits, sedimentary and metamorphic rocks). In seasonally wet soils, carbonate can accumulate in upper subsoils from capillary rise of bicarbonates via evaporative pumping from shallow groundwater.^[7] In addition, carbonate minerals can occur in wetland soils that commonly contain soluble carbonates, bicarbonates, or carbonic acid depending on the pH of the local environment.

Pedogenic vs. Geogenic Carbonate

Many soils develop in calcareous parent materials. For these soils, it has been a challenge quantifying carbonate that formed in the soil profile vs. carbonate mechanically inherited from parent material. Carbonate formed in the soil profile has been termed “secondary,” “authigenic,” or

“pedogenic.”^[4,8] On the other hand, carbonate mechanically inherited from parent material has been termed “primary,” “geogenic,” or “lithogenic.”^[2,9] Criteria for distinguishing pedogenic from geogenic carbonates involve the scrutiny of both field and laboratory evidence. Field evidence, for example, includes differences in the presence of marine fossils, carbonate morphology (such as nodules, pendants, and laminar caps that indicate pedogenic), and distribution patterns with depth, where, e.g., a carbonate horizon of pedogenic origin is overlain and underlain by non-calcareous soil. Laboratory evidence includes comparing mineralogy, particle size, microfabric, and $^{13}\text{C}/^{12}\text{C}$ ratios of carbonate with unknown origin to those of carbonate with known geogenic origin.^[10–12]

Models of Carbonate Formation

There are several processes that cause carbonates to form in soil. Excluding geologic processes, such as lacustrine and deep groundwater cementation that preserve the original sedimentary structure, the formation pedogenic carbonate can broadly be placed into four models—per descensum, per ascensum, *in situ*, and biogenic models.

The per descensum model

The per descensum model accounts for carbonate formation resulting from downward moving meteoric water and can be subdivided into three types. First is the dissolution of preexisting carbonates in the upper profile, their vertical translocation, and their precipitation in the subsoil. This model was invoked to explain why progressively shallower carbonates occur in progressively drier climates.^[13] Later, this per descensum model was used as the basis for calculating the number of wetting fronts required to leach carbonates to a particular depth.^[14] In both cases, it was assumed that carbonate was uniformly distributed in parent material at the beginning of pedogenesis.

Second is the case in which pedogenic carbonate forms in soils with non-calcareous parent materials. Unlike the model described before, non-calcareous parent material does not have carbonate uniformly distributed throughout the profile at the beginning of pedogenesis. In southern New Mexico, e.g., prominent calcic and petrocalcic horizons occur in soils with rhyolite alluvium as parent material. This alluvium would yield low amounts of calcium if the rhyolite particles were thoroughly decomposed, which they were not.^[15] Therefore, atmospheric additions, another per descensum model, were judged to be the source of carbonates.^[15] Initially, calcareous dust was measured and considered to be the source of carbonate. Later it was realized that Ca^{2+} in rain was an additional, and even larger source of Ca^{2+} for reaction with soil HCO_3^- to form carbonates.^[15] Building on these per descensum concepts, compartmental models have been constructed that compute the

depth, amount, and distribution of pedogenic carbonate as a function of climate and time.^[16,17]

Third, in addition to vertical illuviation within a soil profile, lateral, downslope migration of the soil solution containing soluble products of carbonate is another per descensum model. In this case, carbonate is thought to precipitate after carbonate-charged waters migrate from upslope positions to lower landscape positions.^[18]

The per ascensum model

The per ascensum model accounts for carbonate formation resulting from bottom-up movement. A primary example is the capillary rise of Ca^{2+} and bicarbonate from shallow water tables by evaporative pumping, which leads to the precipitation of carbonates in the upper subsoil.^[7] Moreover, chemical studies have shown that in some environments plants promote carbonate formation by transporting Ca^{2+} upward to the land surface from subsoil, rock, and groundwater.^[19]

The *in situ* model

Third, in the *in situ* model, pedogenic carbonate is the result of in-place dissolution and reprecipitation of bedrock composed of marine carbonate.^[20] Limestone, for instance, is progressively transformed into pedogenic carbonate as a result of short-range carbonate dissolution and reprecipitation proximal to the depth of the upper contact with limestone. This is a rather unique method to form pedogenic carbonates where the total carbonate content of the zone of enriched pedogenic products is less than the carbonate content of the limestone originally. These pedogenic zones have a much higher macro- and microporosity than the limestone.

In addition to marine carbonates, the *in situ* model also includes carbonate formation resulting from in-place chemical weathering of Ca-bearing igneous rock. Upon release into the soil solution by weathering, Ca^{2+} precipitates with bicarbonate formed from the reaction of water with CO_2 generated by root and microbial respiration. In many cases, however, igneous parent material has been considered as an insufficient source of Ca^{2+} and hence external sources, such as atmospheric additions of Ca^{2+} , have been sought.^[6]

The biogenic model

Fourth, some plants, microorganisms, and termites produce CaCO_3 . Evidence that various plants play a direct role in carbonate formation comes from the presence of euhedral calcite crystals on plant roots.^[21] Moreover, several references in the Russian literature note carbonate formation by plant tissue and the downward translocation of these carbonates with wetting fronts.^[22] Evidence that some microorganisms precipitate carbonates is based on observations of calcified bacteria and fungal hyphae with electron microscopy and *in vitro* laboratory experiments.^[23,24] Evidence that

termites precipitate carbonate in certain environments is based on the studies of termite mounds in Africa and south-east Asia.^[25] Such mounds can be calcareous even though surrounding soils are non-calcareous, making the mounds attractive to native farmers who spread them over their agricultural fields.^[25]

CONCLUSION

The formation of pedogenic carbonate may be dominated by one of the models listed before or may involve several of the models working together in different magnitudes. Understanding pedogenic carbonate formation has been extremely useful for understanding relative ages of geomorphic surfaces and landscape evolution.^[15] A knowledge of pedogenic carbonate formation has also been useful for soil classification. Marbut,^[26] for instance, used the presence of carbonate as a criterion for the highest category of his soil classification—Pedocal (soils with carbonate accumulation) and Pedalfers (soil with Al and Fe accumulation). Studies of pedogenic carbonate have expanded to include questions about paleoclimate, paleoecology, paleoatmospheric composition, global carbon cycles, and the greenhouse effect.

Inorganic Carbon: Global Carbon Cycle

William H. Schlesinger

Department of Geology and Botany, Duke University, Durham, North Carolina, U.S.A.

Abstract

Changes in the quantity of carbon (C) in vegetation and soils play a major role in determining short- and long-term fluctuations in the concentration of carbon dioxide (CO₂) in earth's atmosphere. Human activities, such as the irrigation of agricultural soils in arid regions, can alter the accumulation of pedogenic carbonate in soils. For comparative purposes, biogeochemists calculate the mean residence time (MRT). Although the amount of pedogenic carbonate in world soils is quite large, this pool of C is relatively sluggish. The long MRT of the pedogenic carbonate pool ensures that it will not become a major sink or source of atmospheric CO₂ over the next several centuries.

INTRODUCTION

The “global C cycle” is defined as the exchange of carbon (C) among the atmosphere, seawater, land vegetation, and soil reservoirs (Fig. 1). Each year dead plant materials entering the soil are decomposed by soil microbes that return carbon dioxide (CO₂) to the atmosphere. If the amount of land vegetation remains the same, the amount of CO₂ removed from the atmosphere by plant growth each year is balanced by the amount of plant death and decomposition. Such a perfect balance, however, is seldom seen. Changes in the quantity of C in vegetation and soils play a major role in determining short- and long-term fluctuations in the concentration of CO₂ in earth's atmosphere. A portion of the atmospheric increase in CO₂, e.g., is because of the destruction of vegetation and the disturbance of soils by humans.

MEAN RESIDENCE TIME (MRT)

For comparative purposes, biogeochemists calculate the MRT or the amount of time C resides in each pool of the global C cycle before circulating to the others. For instance, a molecule of CO₂ spends, in average, about 5 years in the atmosphere before it enters the terrestrial biosphere or the oceans. A C atom spends, in average, about 10 years in vegetation and 35 years in soil organic matter (SOM) before it returns to the atmosphere as CO₂. In comparison, the circulation of C in the oceans is rather sluggish; the C atom spends, in average, hundreds of years in the sea, where it is found predominantly as dissolved bicarbonate (HCO₃⁻). Human activities have the greatest impact on pools with short MRTs.

WEATHERING

Most studies of soil C focus on SOM, which globally contains nearly 2300×10^{15} g C.^[1] The release of CO₂ by the microbial decomposition of SOM is one of the largest fluxes in the global C cycle (Fig. 1). However, soils also contain C in various inorganic forms—CO₂ held in the soil pore spaces, HCO₃⁻ dissolved in soil waters, and calcium carbonate (CaCO₃) as a soil mineral. CO₂ in the soil pores is largely derived from the respiration of plant roots and soil microbes, which varies as a function of soil moisture and temperature. However, even when the respiration rate is very high, the amount of C in soil gases and the soil solution is not large enough to contribute materially to the total C content of soils globally. In contrast, the amount of C held in soil carbonates is quite large, totaling about $750\text{--}1000 \times 10^{15}$ g C (Fig. 1).^[2,3] The vast majority of this carbonate is found in the world's arid and semiarid lands, where inorganic C may exceed soil organic C by a factor of 10.^[4]

In some soils, CaCO₃ and other carbonates (e.g., dolomite) are derived from the parent rocks from which the soils have formed. However, additional carbonate may form as a result of the release of calcium (Ca) from the chemical weathering of rocks and the precipitation of CaCO₃ when water is lost from the soil by evaporation and plant uptake. In the case of silicate parent minerals, such as plagioclase (calcium feldspar), the relevant reaction of weathering is as follows:

Here Ca is released from the silicate mineral by the weak solution of carbonic acid that is formed when CO₂ dissolves in water.

Fig. 1 The global C cycle, showing the size of reservoirs (10^{15} g C) and the annual flux between them (10^{15} g C/yr).

Source: Modified from Schlesinger.^[9]

Declining soil concentration of either CO_2 or water precipitates carbonate via the following reaction:

While the weathering process occurs most rapidly when plant activity increases the concentration of CO_2 in the soil pore space, the precipitation reaction occurs during seasonal periods of drought. Carbonate formed in the soil, known as secondary or “pedogenic” carbonate, can be distinguished from carbonate inherited from parent materials by examining thin sections and the isotopic ratio (^{13}C vs. ^{12}C) of the C in carbonate minerals.

ATMOSPHERIC DERIVATION

In most areas, the Ca content of pedogenic carbonate is derived from the atmosphere and is deposited as a constituent of rain and dust.^[5,6] However, because the Ca carried in the atmosphere is ultimately derived from the weathering of rocks in some upwind area, the two aforementioned reactions are general.^[7] Across deserts of the Southwestern United States, the formation of pedogenic carbonate is closely related to mean annual rainfall (Fig. 2).

If we know the rate of formation of pedogenic carbonate, usually expressed in grams per square meter per year ($\text{g/m}^2/\text{yr}$), and the total amount of carbonate in the soil profile, we can calculate the length of time taken for the accumulation of current quantity of soil pedogenic carbonate. In the Mojave Desert of California, radiocarbon and uranium–thorium dating show that pedogenic carbonate found in the upper 1.5 m of soils, derived from silicate materials, accumulated over a period of up to 20,000 years.^[8] During that period, pedogenic carbonate formed at rates ranging from 1.0 to 3.5 $\text{g/m}^2/\text{yr}$, with some indications of greater rates during the Pleistocene, when rainfall was greater in this region. The global MRT of soil pedogenic carbonate is about 85,000 years, making this C pool

much less dynamic than SOM, in which the global MRT for C is about 35 years (Fig. 1).

While CO_2 is sequestered from the atmosphere during the formation of pedogenic carbonate from silicate parent materials, no such net storage occurs when pedogenic carbonate forms from carbonate parent materials.^[10] Overall, the formation of soil pedogenic carbonates is less effective than the formation of SOM in the storage of atmospheric CO_2 .^[11] This is disappointing, of course, to those who view increasing the formation of pedogenic carbonate in desert soils as a means of slowing the rise of CO_2 in the earth’s atmosphere and reducing global warming.

EFFECT OF HUMAN ACTIVITIES

Human activities, such as the irrigation of agricultural soils in arid regions, can alter the accumulation of pedogenic

Fig. 2 The rate of formation of pedogenic carbonate in arid soils of the Southwestern United States as a function of the modern precipitation at each site.

Source: From Marion.^[12]

carbonate in soils. The groundwater used for irrigation is often extracted from subsurface environments, where CO₂ concentration is much higher than in the earth's atmosphere, and often contains high concentrations of dissolved Ca. Applying such water to arid lands precipitates dissolved Ca in the soil, thereby forming CaCO₃, and releases CO₂ to the atmosphere, via the reaction in Eq. 2. The precipitation of calcite is also favored when large amounts of gypsum (CaSO₄ · 2H₂O), a ready source of Ca, are used to remediate dryland soils. The formation of pedogenic carbonate in arid, agricultural soils, as a result of these human activities makes a small contribution to the increase in atmospheric CO₂.^[13]

Human activities leading to the formation of acid rain also affect soil carbonates. If the acidity in rainfall is derived from sulfuric acid (H₂SO₄), then CO₂ is released when the rain falls on carbonate-rich soils. The reaction is as follows:

Gypsum (CaSO₄ · 2H₂O) precipitates as the soil dries. Although most fossil fuels contribute small amounts of sulfur to the atmosphere, the global amount of CO₂ derived from this reaction is relatively small compared to the direct release of CO₂ from fossil fuel combustion (Fig. 1).

CONCLUSION

Although the amount of pedogenic carbonate in world soils is quite large, perhaps as much as 1000×10^{15} g C, this pool of C is relatively sluggish. The long MRT of the pedogenic carbonate pool ensures that it will not become a major sink or source of atmospheric CO₂ over the next several centuries.

Abstract

There is a very large global pool of soil inorganic carbon (SIC), but its formation, quantity, and dynamics are uncertain. The major problems in determining SIC stocks are the incomplete global database and the difficulty in separating pedogenic from lithogenic carbonate sources.

INTRODUCTION

More work has focused on the role of soil organic carbon (SOC)^[1–5] than soil inorganic carbon (SIC)^[6,7] in the global carbon cycle. One of the constraints to quantifying SIC stocks is the incomplete global dataset. Thus, we can estimate global SIC stocks but with considerable uncertainty. Further, there is difficulty in differentiating lithogenic from pedogenic carbonates because most routine chemical methods determine the total quantity of carbonates in a soil sample without regard to origin. The amount of pedogenic carbonate formed in soils is typically estimated from visible segregations in the field, from chemical analysis in the laboratory under the assumption that the carbonate is pedogenic,^[8] or from stable carbon isotope analysis to differentiate lithogenic from disseminated pedogenic carbonate components.^[9] Gile and Grossman^[10] consider that much of the calcium in carbonates results from carbonate dusts or from calcium in rainwater. Chadwick and Capo^[11] believe that at least 95% of the Ca in carbonates of arid and semiarid regions is derived from dusts. Many soils also have lithogenic carbonate inherited from alluvial, till, and bedrock parent materials. It is possible that as little as 10% of the total SIC reported in soils is formed from the authigenic weathering of calcium-bearing minerals.

Perhaps even less well understood are the flux rates of SIC stocks (e.g., soluble carbonates, bicarbonates, and carbonic acid) from soil systems into the vadose zone, geologic substrata, ground water aquifers, rivers, lakes, and oceans. The flux rates of inorganic carbon stocks require knowledge of soil chronology coupled with mass balance reconstruction analyses to determine the magnitude of

gains or losses.^[12,13] This long-term transitory SIC stock is believed to have important impacts on soil carbon sequestration over geologic time periods up to 10 times longer than the SOC stocks.^[12–14] Also, the biogenesis of SIC stocks by various organisms (e.g., plant roots, blue green algae, termites, plankton, etc.), while well documented, is not as well quantified.

MORPHOLOGY OF SIC STOCKS

The major SIC stocks are in petrocalcic and calcic horizons. It is estimated that calcic horizons contain 209 Pg C (10^{15} g C), petrocalcic horizons 104 Pg C, and calcareous soils not meeting the taxonomic criteria for a named carbonate horizon about 636 Pg C.^[6] Disseminated carbonates (micritic or fine-grained carbonate particles) and segregated forms of soft masses, threads, films, or filaments are often present in soils at quantities insufficient to be recognized as calcic horizons.^[8] Such disseminated and segregated carbonates may be the most chemically reactive form of SIC.

MAGNITUDE OF SIC STOCKS

The amount of soil global inorganic carbon is large, with estimates ranging from 1576 to 695 Pg C.^[3,15,16] Eswaran et al.^[17] revised the estimates down to between 949 to 940 Pg C, which appear to be more reasonable (see [Tables 1](#) and [2](#)). Uncertainties in these numbers result because the depth of the soil represented has been arbitrarily set at 1 m, the values represent combined lithogenic and pedogenic sources, and the data for SIC stocks that are partitioned by soil taxa and global areal extent are approximate.

Table 1 SIC and TC in soil orders of soil taxonomy

Discrepancies in areal extents of soil orders/suborders, and the SIC stocks in Tables 1–4, are due to rounding errors and different sources of published information.

SIC STOCKS RELATED TO SOIL TAXONOMY ORDERS AND SUBORDERS

Areal stocks of SIC in soil orders are presented in Table 1 and partitioned by the suborders of soil taxonomy in Table 2.^[8] About 38% of the total carbon (TC) stocks are accounted for by SIC, with Aridisols, Entisols, and Mollisols contributing the most (Table 1). Nearly half of the SIC occurs in Aridisols (Table 1) with over 85% distributed among Argids, Calcids, and Cambids (Table 2). Entisols contain 28% of SIC (Table 1) with 77% associated with Orthents (Table 2). Mollisols contain the next largest amount of SIC (≈12%) with over 80% stored in Ustolls. The Alfisols contribute nearly 5% of the SIC stocks with over 95% stored in Ustalfs and Xeralfs. These distributions of SIC stocks reflect heavily on the semiarid and drier climates, coupled with carbonate-rich parent materials.

Five of the soil orders contain no SIC stocks. These orders are the Andisols, Histosols, Oxisols, Spodosols, and Ultisols. They represent soils in subhumid to humid environments where carbonates have been leached into lower vadose zones, geologic substrata, and/or ground water aquifers. In these orders one would expect the parent materials to have been either non-calcareous or low in carbonate content.

The ratios of SIC/TC as a percentage of the order and as a global percentage are given in Table 1. It is noteworthy

that nearly 90% of the TC is SIC in Aridisols, 75% of the TC is SIC in Entisols, and about 50% of the TC is SIC in Mollisols. This reflects environments that do not favor sequestration of SOC because the soils are youthful, well oxidized, and have primary productivity constrained by long periods of soil moisture stress.

SIC STOCKS RELATED TO SOIL MOISTURE CONDITIONS

Table 3 presents SIC and TC stocks according to global soil moisture and temperature conditions. Two soil moisture

Table 3 SIC and TC stocks according to moisture conditions.

Moisture condition	TC		SIC		SIC/TC % region	SIC/TC % global
	Pg	% Global	Pg	% Global		
Permafrost	405	16.4	18	1.9	4.4	0.7
Arid	877	35.5	732	77.8	83.5	29.7
Mediterranean	90	3.6	50	5.4	55.6	2.0
Semiarid	471	19.1	134	14.2	28.5	5.5
Humid	539	21.9	4	0.5	0.7	0.2

Total	2472	100.0	946	100.0	38.2	

Source: From Eswaran, Reich, et al.^[17]

conditions account for 92% of the SIC stocks, namely arid ($\approx 78\%$) and semiarid ($\approx 14\%$). This is explained by the fact that these environments exhibit little soluble transport of pedogenic and lithogenic carbon stocks. In these environments, the proportion of TC, i.e. SIC, is $\approx 84\%$ and $\approx 29\%$, respectively, indicating that accumulation of SOC is not as important in these dry climates as in humid and wetter regimes where SOC comprises $\approx 97\%$ of the TC stock (Table 3). It is interesting to note that in Mediterranean climates with winter rain, SIC contributes $\approx 56\%$ of the TC stock. Again, because of the semiarid condition the SOC pool is less important than SIC. From the above comments, it is not surprising that a little over 38% of the TC stock (2472 Pg C) is SIC (946 Pg C), with arid (30%) and semiarid (6%) regions serving as major contributors.

SIC STOCKS RELATED TO ECOLOGICAL REGIONS

Table 4 illustrates SIC and TC stocks partitioned by ecological regions. Boreal and temperate regions contribute $\approx 82\%$ of the global SIC, with tropical regions $\approx 16\%$ and tundra regions $\approx 2\%$. The SIC is much higher in the temperate region (55%) due to the larger extent of deserts. The small contributions of SIC to TC in tundra regions reflect cold temperatures favorable to SOC

Table 4 SIC and TC stocks according to ecological regions.

Ecological region	TC		SIC		SIC/TC % Region	SIC/TC % Global
	Pg	% Global	Pg	% Global		
Tundra	405	16.4	18	1.9	4.4	0.7
Boreal	632	25.6	256	27.2	40.5	10.4

accumulation and dissolution of lithogenic SIC. Many of the tropical regions are more humid, and thus any SIC in the soil parent materials has been leached.

FLUX OF SIC STOCKS

An estimate of soluble carbonate fluxes can be made from mass balance reconstruction analysis of the soil carbonate phase. Two problems with this method are the lack of reliable estimates of soil chronology and assumptions of flux rates. The rates of soil genesis, and especially the more labile carbonate components, are known to be exponential functions, but the precise geometric rate function applicable is not known and would vary with different amounts of carbonate, carbonate mineralogy, leaching potential, soil temperature, soil permeability, and vegetative cover.

The magnitude of leaching of soluble carbonates and bicarbonates has been estimated globally from calcareous soils.^[12,13] These projections are based on a flux rate of between 7 and 8 g m⁻² yr⁻¹ from soil great groups likely to have leaching potentials sufficient to transport soluble products of carbonate weathering from the soil. Estimated results indicate that between 0.25 Pg and nearly 0.40 Pg of SIC is lost per year globally in leaching calcareous environments. The major contributors to these leachates are the Entisol, Mollisol, and Alfisol soil orders. This value probably underestimates the actual flux of SIC stocks because it does not consider the amount of carbonic acid used to weather soil minerals or the amount that is flushed from soils of high leaching potentials, such as, Oxisols, Ultisols, and Spodosols, which occupy about 20% of the ice-free earth's surface.

CONCLUSION

There is a very large global pool of SIC, but its formation, quantity, and dynamics are uncertain. The major problems in determining SIC stocks are the incomplete global database and the difficulty in separating pedogenic from lithogenic carbonate sources. To provide better estimates of SIC stocks, more sampling and analysis are needed that involve good soil chronology, stable carbon isotopes to differentiate pedogenic from lithogenic carbonates, and techniques to quantify soluble SIC stocks.

Inorganic Carbon: Land Use Impacts

Donald L. Suarez

U.S. Salinity Laboratory, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Riverside, California, U.S.A.

Abstract

Land use affects soil inorganic carbon (C), but the changes are significant only over the long term. Both increases and decreases in C storage occur as a result of various management practices. In irrigated lands, the primary factors causing a decrease in inorganic C are high leaching and maintenance of elevated water content at or near the soil surface. These factors result in elevated carbon dioxide (CO₂) concentrations and thus increased dissolution of soil carbonates. Use of acidifying fertilizers such as ammonia and sulfur also act to reduce soil inorganic C. Practices that favor accumulation of carbonates in the soil include efficient irrigation with surface waters in arid and semiarid regions (leaching less than 30% of the applied water), irrigation with ground waters at elevated CO₂ concentrations, application of gypsum to alkaline soils, and use of nitrate fertilizer. Other factors that affect soil carbonate content include land clearing, cropping practices, and erosion.

INTRODUCTION

Soil inorganic carbon (C) constitutes a major C pool in the near surface environment. In arid regions, the inorganic C can comprise more than 90% of the total C in the soil. The major inorganic C mineral phases are calcite and dolomite. Both minerals are relatively insoluble, however, dolomite dissolution is much slower than calcite dissolution at the intermediate pH values relevant to soils. Also, dolomite does not readily precipitate under earth surface conditions. As a result, dolomite content in soils will remain constant or decrease due to dissolution, while calcium carbonate content may either increase or decrease.

LAND CLEARING AND CROPPING

Land clearing generally results in increased water runoff and soil erosion. This process or any other process such as tillage that increases erosion serves to remove the surface soil horizons. Since these horizons are generally depleted in inorganic C relative to less weathered, deeper horizons, there is an apparent increase in the inorganic C content of the surface soil as a result of erosion. In terms of carbonate dissolution, the impact of land clearing is not certain. After clearing there is increased runoff, thus decreased infiltration, favoring less dissolution of carbonates. This effect may be compensated by the decreased water consumption (lower evapotranspiration) after clearing, resulting in increased deep recharge (greater carbonate dissolution). Depending on how much biomass remains after clearing, there is likely a short-term increase in soil CO₂ followed by a longer term reduction, favoring less carbonate dissolution

in the soil. Land clearing and overgrazing in arid lands serve to increase wind erosion and to redistribute soil in the landscape. In this manner, non-calcareous soils receive inputs of carbonates. This process increases net dissolution of carbonates in the landscape.

In humid environments, inorganic C is leached from the soil. The elevated CO₂ concentrations in the soil enhance calcite solubility relative to earth surface conditions. In humid environments, carbonates are successively leached from the upper portions of the soil profile. Agricultural practices may serve to enhance or reduce the net removal of carbonates. Removal of vegetation from a site with practices such as tree harvesting or harvesting of forages serves to remove base cations and causes net acidification of the upper portions of the soil profile. If carbonates are present deeper in the soil, this acidification increases dissolution. The impact of removal of vegetation in humid environments with carbonates in the subsoil can be calculated by assuming that the net harvested alkalinity is compensated by an equal increase in carbonate dissolution in the subsurface.

FERTILIZATION

Since optimum plant growth is generally at a pH lower than that observed in untreated calcareous soils, acid fertilizers are commonly applied. Use of sulfur with subsequent oxidation to sulfate results in acid release to the soil (2 mol of protons per mole of sulfur). Application of ammonia salts, with subsequent fixation into organic matter or oxidation to nitrous oxide or elemental nitrogen, also releases protons (2 and 1 mol of protons per mole of ammonia ions,

respectively). This acidification will increase carbonate dissolution proportionately and has a significant effect, since ammonia salts are widely used.

Application of urea or ammonia gas should have no net effect on carbonate dissolution (upon oxidation to nitrous oxide or elemental nitrogen). In contrast, use of nitrate fertilizers serves to increase pH and thus reduce carbonate dissolution. Generally nitrate is not utilized on calcareous soils, so the impact on inorganic C storage in soil is slight. The quantitative impact of fertilization on changes in inorganic C is not easily calculated, as it depends on the extent of N incorporation into organic matter, mineralization, the extent to which the harvested biomass is removed from the site, and the occurrence of carbonates in the subsurface. The addition of liming products, primarily calcite, are reported as 3.7 Tg C yr^{-1} in the United States for 1978.^[1] This is a significant but temporary addition to the soil C pool as it is assumed that the majority of the material is applied to acid soils and thus it is readily dissolved.

HUMID REGION IRRIGATION

Irrigation in humid environments serves to increase the net recharge through the soils and thus should increase the removal of carbonates. These changes may be relatively difficult to detect in view of the limited amount of irrigation water added, and the fact that irrigation in humid environments, although increasing rapidly, was very limited in the past. Field studies are needed to determine the impact of irrigation on changes in inorganic C storage in humid environments.

ARID REGION SOILS

Arid zone soils usually contain at least minor amounts of carbonates, even if classified as non-calcareous. In the absence of irrigation, there may be redistribution of carbonates within the soil but little net precipitation. The majority of the pedogenic calcite is reprecipitated calcite with relatively small amounts added as a result of mineral weathering. Significant amounts of carbonates are also added to the surface of arid land soils as dust. Calcite is leached from the upper part of the soil profile by dissolution into the infiltrating rain and is mostly reprecipitated at depth after plant extraction of the available water.

Irrigation in arid and semiarid environments may result in a net increase or decrease in soil carbonate, depending on the water source and fraction of water applied that is leached (leaching fraction). There are two opposing effects. First, elevated CO_2 concentrations in the root zone relative to the atmospheric condition results in enhanced calcite solubility and dissolution. Second, plant water extraction and evaporation concentrate the salts into a smaller volume of water and enhance calcite precipitation. At low leaching fractions, the effect of concentration of salts due to plant

water extraction and evaporation is greater than the enhanced CO_2 effect, and there is net precipitation of calcite.

For a calcite-saturated surface water such as the Colorado River, it is estimated^[2] that at a leaching fraction of 0.1 there is net precipitation of $125 \text{ kg ha}^{-1} \text{ yr}^{-1}$ of C, based on water consumption of 1.2 m yr^{-1} and a CO_2 partial pressure of 3 kPa. Model simulations indicated that net precipitation of calcite occurred as the sum of the loss of carbonates in the upper portion of the root zone and precipitation of calcite in the lower portion. At high leaching fractions, there is net dissolution of carbonates. Using a calcite equilibrium model, it is predicted that at a leaching fraction of 0.4 there will be a net dissolution of carbonates of $70 \text{ kg ha}^{-1} \text{ yr}^{-1}$ of C, again, based on water consumption of 1.2 m yr^{-1} and CO_2 partial pressure of 3 kPa.^[3] In all instances, there is a prediction of net dissolution in the upper portion of the soil profile and net precipitation in the lower portions of the profile. Using average leaching fractions for the Western United States, it is estimated that irrigation with surface waters on 12 million hectares results in an increase in inorganic C of $1 \text{ Tg yr}^{-1[4]}$ or $80 \text{ kg ha}^{-1} \text{ yr}^{-1}$.

Irrigation with groundwater saturated with respect to calcite will result in precipitation of carbonates at almost all leaching fractions, since the irrigation water is equilibrated at the groundwater CO_2 partial pressure and is supersaturated upon degassing and application to the soil. Calcite-saturated groundwater is used for irrigation on an estimated 3.12 million hectares in the United States. It is estimated that irrigation on these soils results in a net inorganic C precipitation of 1.3 Tg yr^{-1} or $420 \text{ kg ha}^{-1} \text{ yr}^{-1}$.^[3] The above calculations are dependent on several assumptions regarding calcite equilibrium and soil CO_2 concentrations. Using a kinetic model for calcite precipitation and the measured CO_2 partial pressure in the groundwater in Palo Verde Valley, there is prediction of no net change in inorganic C at a leaching fraction of 0.5. Consistent with these predictions, the groundwater composition in Palo Verde Valley shows no evidence for net precipitation or dissolution of carbonates in the soil.

There is limited direct field evidence for the influence of irrigation on inorganic soil C, and it is difficult to be certain that differences among sites are only related to changes in management. Researchers^[4] observed a net decrease in the calcium carbonate content of three pairs of soil profiles taken from sites in Israel irrigated for approximately 40 years as compared to non-irrigated sites. The estimated input of 4.40 m of water per year at those sites is contrasted with the yearly potential evapotranspiration of 1.93 m. The observed trend is qualitatively consistent with model predictions, if we account for the input of rain and the estimated leaching fraction of 0.56. Isotopic evidence indicated that there was precipitation of pedogenic carbonate at depth, despite a net decrease in carbonate content at depth.

In a study in the San Joaquin Valley in California, researchers compared samples of a soil taken from irrigated

and native vegetation sites.^[5] They also measured a net loss of carbonates attributed to 8 years of irrigation. Net carbonate loss was estimated as $7 \times 10^3 \text{ kg ha}^{-1} \text{ yr}^{-1}$ ($800 \text{ kg C ha}^{-1} \text{ yr}^{-1}$). Leaching fractions at the site were not reported but this value corresponds to approximately 10 times greater dissolution than expected based on model simulations. However, another study by the same author^[6] found no change in total carbonate when comparing pedons with native vegetation and those irrigated for 5–25 years. In this instance, both gypsum and sulfur were applied as amendments for reclamation. Gypsum would tend to increase precipitation of carbonates, while sulfur would acidify the soil and cause net dissolution of carbonates. In an extensive study^[7] on paired soil cores (irrigated and adjacent nonirrigated sites) from the lower Colorado River basin, there were no observed changes in net inorganic C storage after 90 years of irrigation, and no isotopic C shifts indicative of recrystallization.

SODIC SOIL RECLAMATION

Reclamation of sodic soils can result in either an increase or decrease in inorganic C in the soil. Gypsum application to a sodic and alkaline soil will increase the soil carbonate content, as the increased Ca will precipitate most of the soluble bicarbonate and carbonate. Application of sulfuric acid, sulfur, or green manuring all serve to dissolve soil carbonates. Green manuring as a reclamation practice consists of incorporating plant residues into the soil and leaching with water. The high CO_2 production is combined with restricted gas transport creating very high CO_2 concentrations in the soil, dissolving large amounts of calcium carbonate. It is estimated that this process can dissolve in the order of $400\text{--}800 \text{ kg ha}^{-1}$ during a year of reclamation. Use of acid is a widespread and generally recommended practice to prevent emitter clogging in drip irrigation systems. This practice may result in total removal of carbonates within 10–20 years, for soils with less than 3% carbonate content.

IMPACT ON ATMOSPHERIC CARBON DIOXIDE (CO_2)

Dissolution of carbonates in neutral to alkaline environments results in consumption of CO_2 gas and formation of aqueous HCO_3^- , while precipitation of carbonates results in release of CO_2 . The net effect of dissolution or precipitation of soil carbonate on atmospheric CO_2 depends on the solution flow path. In regions irrigated with surface water, the dissolution of carbonates results in a net C sink. However, the high alkalinity drainage water usually flows

back to the river. The resultant degassing of carbonic acid and reprecipitation of carbonate in the river or reservoir releases CO_2 back into the atmosphere. If the water is recharged into deep aquifers, the net soil flux is preserved. In acid environments, liming of soils results in CO_2 release to the atmosphere, as there is little or no net alkalinity produced.

CONCLUSION

Land use practices have a long-term impact on soil inorganic C. Due to the large C pools in the soil, these impacts are not generally observed in short-term studies. In humid environments, the major anthropogenic impacts on inorganic C are liming of surface soils, use of ammonium (NH_4) vs. nitrate fertilizer, removal of vegetation, and erosion. In semiarid and arid environments, increased inorganic C is favored by the use of groundwater for irrigation and application of gypsum. Decreased inorganic C is favored by inefficient irrigation with surface water and application of NH_4 fertilizer. The net effect of irrigation on a global scale, neglecting the effects of fertilizer addition, is to increase soil inorganic C by 30 Tg C yr^{-1} as well as to release an equal amount of C to the atmosphere. Liming practices in humid regions throughout the world are estimated to have no net effect on inorganic soil C but release up to 85 Tg C yr^{-1} to the atmosphere.

Abstract

Developing a numerical model of carbonate accumulation is a challenging proposition, given the remarkably complex character of the soil system. Numerical models and isotope studies have proven to be valuable tools in the study of calcic soil development. They have helped elucidate the relation of climate, vegetation, and geomorphic processes to carbonate accumulation.

INTRODUCTION

Virtually all carbon in soils of arid and semiarid regions of the world accumulates as pedogenic calcium carbonate (CaCO_3 , referred to subsequently as carbonate). The carbonate usually accumulates in layers that eventually attain the status of calcic horizons and, in much older soils, petrocalcic horizons. Numerous mechanisms for the accumulation of pedogenic carbonate in soils are recognized, but the most fundamental reason for accumulation is limited depth of soil–water movement and seasonally high evapotranspiration that favors precipitation of carbonate within the soil.^[1] Many studies of calcic soils in the past few decades demonstrate a close correspondence between the depth of pedogenic carbonate accumulation and modern annual precipitation,^[2–4] although few studies show the relationship may be more complicated.^[5] Other studies also show progressive, time-dependent accumulation in many environments;^[1] these studies have led to the generally accepted conceptual models of calcic soil development.^[6]

Development of a numerical model of carbonate accumulation, however, is a more challenging proposition, given the remarkably complex character of the soil system. Fortunately, certain aspects of calcic soils facilitate formulation of such numerical models. For example, the observed soil depth–climate relationship implies that, utilizing a sound strategy for simulation of water movement, determination of carbonate movement via solution transport is a reasonable proposition. In addition, a significant body of research shows that the majority of carbonate is derived from accumulated entrapped dust and calcium in rainwater.^[1] Finally, data pertaining to calcite geochemistry and dissolution rates in different environments are available and show that, in soils associated with typical ranges in soil carbon dioxide (CO_2), pH, and salinity, calcite is far more

soluble than virtually all silicate minerals and has more rapid dissolution rates.^[7] Consequently, a relatively simple model for carbonate movement in a soil based on relations in the $\text{CaCO}_3\text{--H}_2\text{O--CO}_2$ system can be formulated that essentially ignores the more complex chemical reactions involving aluminosilicates. Research on the nature and composition of stable and unstable isotopes in pedogenic carbonate has also helped elucidate the nature of calcic soil development and improve the design for testing the results of numerical modeling.

THE COMPARTMENT MODEL AND SIMULATIONS OF PEDOGENIC CARBONATE ACCUMULATION

The compartment-model, or “box-model,” approach to modeling of calcic soils accommodates continuously changing values among the interdependent variables that influence soil development. It enables integration of several factors that influence pedogenic carbonate accumulation and that can be explicitly considered in this model. These include soil–water movement and soil–water balance, changing soil CO_2 concentrations and temperature with depth and season, initial parent material composition, carbonate and soluble salt additions from external sources, and calcite reactant surface area. The soil profile is represented by a vertical sequence of compartments of arbitrary dimensions, with the initial characteristics of each compartment specified [i.e., texture, available water-holding capacity, and partial pressure CO_2 ($p\text{CO}_2$)]. A series of equations that enable forward modeling and simulation of evolving carbonate depth functions using the box-model approach can be derived on the basis of consideration of the factors indicated above. For example, the solubility of calcite is derived from the following equation, after Drever:^[8]

$$m^3 \text{Ca}^{2+} = \frac{(p\text{CO}_2 K_1 K_{\text{cal}} K_{\text{CO}_2})}{(4K_2 \gamma \text{Ca}^{2+} + \gamma^2 \text{HCO}_3^-)} \quad (1)$$

where K_{cal} is the calcite solubility product, K_1 , K_2 , and K_{CO_2} are dissociation constants in the carbonate system, and γCa^{2+} and γHCO_3^- are the activity coefficients of Ca^{2+} and HCO_3^- . A gravelly, permeable calcic soil probably best approximates an open system-weathering environment, in which case calcite dissolution rates are probably surface area controlled rather than diffusion controlled. Also, the dissolution rate is defined ultimately by the rate-limiting conversion of dissolved carbon dioxide (CO_2^*) to carbonic acid (H_2CO_3). At a very low solution volume to surface area ratios, and with fast, surface-controlled calcite dissolution rates, H_2CO_3 is rapidly depleted. In such circumstances, a commonly used rate equation that enables determination of dissolution rates in the CO_2 - CaCO_3 - H_2O system^[9] is

$$dC/dt = (A'k/V)(1 - C/C^*)^n \text{ mg l}^{-1} \text{ s}^{-1} \quad (2)$$

where A' is the surface area of rock in contact with water (cm^2), V the water volume (cm^3), k the reaction coefficient ($\text{mg cm l}^{-1} \text{ s}^{-1}$), n the reaction order, C the moles of calcite in solution, and C^* is the solubility of calcite. Values of n and k vary with saturation ratio, temperature, and $p\text{CO}_2$. In the model, A'/V can be specified depending on observed soil features. Eqs. 1 and 2 show that soil CO_2 content is a very important variable, but soil CO_2 contents may be highly variable.^[10] Fortunately, studies show that a depth function for $p\text{CO}_2$ that reflects prolonged seasonal respiration levels can be estimated, assuming the concentration of soil CO_2 is described by mass transport of CO_2 by gas diffusion.^[11,12] The following diffusion reaction equation, essentially Fick's Second Law for a one-dimensional case, is used in the model:

$$\partial C_s / \partial t = D_s (\partial^2 C_s / \partial z^2) + \phi_s(z) \quad (3)$$

where C_s is the concentration of CO_2 in the soil (mol cm^{-3}), t the time (s), D_s the diffusion coefficient for CO_2 in the soil ($\text{cm}^2 \text{ s}^{-1}$), z the depth in the soil (cm), and $\phi_s(z)$ is the production rate of CO_2 as a function of depth ($\text{mol cm}^{-3} \text{ s}^{-1}$). At steady state, when $\partial C_s / \partial t = 0 = D_s \partial^2 C_s / \partial z^2 + \phi_s$, the general solution to this equation to produce a simple production function is

$$C_s(z) = \phi / D_s (Lz - z^2/2) + C_0 \quad (4)$$

where C_0 is the concentration of CO_2 in the atmosphere (ppm) and L is the depth to the lower, no-flux boundary. Soil CO_2 contents with depth calculated using this method are used to calculate carbonate solubility and dissolution rates with depth.

Available water-holding capacity, infiltration, and percolation rates can be specified on the basis of laboratory soil measurements or estimated from field measurements or theoretical considerations.

Earlier versions of the simulation model included certain assumptions that simplified numerical calculations, such as simple vertical saturated flow and constant soil temperature with depth. The lack of certain types of data (e.g., variation of $p\text{CO}_2$ with depth and time of year) also constituted a limitation on utility of the model. The model did enable simulation of: 1) realistic depths and magnitudes of carbonate accumulation over thousands of years and 2) the range of effects of large climatic changes on calcic soils.^[13–16] Model results emphasized the critical roles of external Ca^{2+} influx and influence of soil CO_2 concentrations on carbonate accumulation. Model-simulated bimodal concentrations of carbonate based on theoretical, late-Pleistocene climatic conditions resembled those observed in late-Pleistocene, polygenetic soils; however, incompletely understood changes in the magnitude of climate changes, dust flux, and vegetation change in the Quaternary complicate attempts to simulate polygenetic soils.^[7,14,16]

Later versions of the model utilized important new inputs and employed routines that reflected improved understanding of key processes that strongly influence calcic soils. Studies of dust accumulation rates in the American Southwest,^[17] C, O, and Sr isotopes in carbonate and the development of more sophisticated models for unsaturated flow in calcic soils^[18] have allowed development of improved compartment models that can address new and more challenging research problems. For example, such numerical simulations demonstrate how climate changes in the Holocene might have dramatically influenced the rates and temporal patterns of soluble salt leaching and accumulation relative to pedogenic carbonate.^[19] A modeling study addressed the problem of how carbonate can occasionally accumulate at much shallower depths than those expected from the depth—annual leaching depth relationship.^[20] This study showed how carbonate can be preferentially removed from depths of a few centimeters to a few decimeters below the soil surface, while carbonate simultaneously accumulates either as collars on surface pavement clasts or in the vesicular A horizon. Model results also explain how a significant change in climate or soil erosion rates could cause the dissolution of carbonate rinds on the tops and sides of boulders and/or the tops of limestone boulders at depths of up to several decimeters, unusual features observed in some calcic soils.^[21]

ISOTOPES IN CALCIC SOILS

During weathering, parent material carbonate undergoes dissolution and reprecipitation in the soil. The carbon ($^{13}\text{C}/^{12}\text{C}$ and $^{14}\text{C}/^{12}\text{C}$) and oxygen ($^{18}\text{O}/^{16}\text{O}$) isotope ratios of pedogenic carbonate that forms from dust or parent material carbonate, or from Ca^{2+} derived from silicate weathering, are determined by isotopic composition of soil CO_2 and H_2O . These are the primary carbon and oxygen reservoirs, respectively, for the carbonate. Therefore,

pedogenic carbonate reflects only isotopic conditions of the soil and bears no memory of the isotopic composition of the rock or mineral from which it was derived.

Soil CO₂ is derived primarily from decomposition of soil organic matter and root respiration. The C isotope composition of soil CO₂ reflects: 1) the isotopic composition of these CO₂ sources; 2) the effects of the diffusion of this CO₂ toward the atmosphere; and 3) the isotopic composition of atmospheric CO₂. In the 1980s, researchers recognized that fairly simple, steady state, diffusion models could be used to reasonably explain the observed depth patterns of C isotopes in both soil CO₂ and pedogenic carbonate. The solution to the mathematical model that encompasses the a forementioned processes describes the abundance of ¹²CO₂ in soils. A related equation can be derived for ¹³CO₂, and the ratio of the two models then describes the ratio of C isotopes at any given soil depth. A similar approach can also be used to model the ¹⁴C composition of CO₂ with soil depth, with the additional complication that the two main sources of soil CO₂ (humus decomposition and root respiration) have different ¹⁴C contents, making the solution to the model slightly more complex.^[22] The C isotope diffusion model of soil CO₂ has provided the opportunity to quantitatively use pedogenic carbonates in a number of applications: 1) paleovegetation studies;^[23] 2) paleo-atmospheric CO₂ studies;^[24] and 3) radiocarbon dating of pedogenic carbonate and geomorphic surfaces.^[25,26]

The O isotopic composition of soil water is determined by the O isotope composition of precipitation and the evaporation of soil water. It has been observed that the ¹⁸O content of modern precipitation is generally correlated with mean annual temperature on a global scale,^[27] but regional differences due to storm sources can obscure these patterns.^[28] If precipitation water (once stored in the soil) is subject to evaporation, an enrichment of the remaining soil water in ¹⁸O occurs because water vapor depleted in the “heavy” isotope is preferentially removed during evaporation. Models have been made that successfully explain the key components of this process^[29] and the fact that soils subject to evaporation commonly have generally decreasing ¹⁸O contents of soil water with depth.^[30] These models have two components. The first is a vapor transport layer (describing the flow of evaporating soil water to the atmosphere through a dry soil layer), and the second is an evaporating front layer. The evaporating front layer exists below the vapor transport zone. At the evaporating front, ¹⁸O enrichment of soil water occurs as water is transferred to a vapor phase, and the remaining ¹⁸O-enriched soil water at the evaporating front then undergoes diffusional mixing with the less ¹⁸O-enriched water at greater depths. In general, these models have been more difficult to use than C isotope models due to the dynamic nature of soil water (steady state assumptions are difficult to apply) and the array of model parameters, many of them not known with certainty for most soils.

Oxygen isotopes in pedogenic carbonate have been used less extensively in paleoclimate work than C isotopes because of concern over possible evaporation of soil water that formed the carbonate. Amundson et al.^[28] demonstrated that, except for hyperarid regions, the O isotope composition of pedogenic carbonate appears to reasonably reflect that of the local precipitation. There is a growing list of studies using carbonate O isotopes in Quaternary^[28] and Tertiary^[31] paleoclimate applications.

CONCLUSION

Numerical models and isotope studies have proven to be valuable tools in the study of calcic soil development. They have helped elucidate the relation of climate, vegetation, and geomorphic processes to carbonate accumulation. The models are not able to explain the observed character of certain aspects of calcic soils, such as patterns of pedogenic carbonate development in some soil chronosequences,^[32] or the somewhat enigmatic formation of calcic soils in humid, monsoonal climates. Also, these models are not designed to simulate the evolution of very old, morphologically complex soils with petrocalcic horizons. Future models must be designed to address locally abundant calcic soils. Additional fieldwork and application of developed field and laboratory techniques will provide the basis for development of the next generation of numerical models.

Insect Survival: Subzero Temperature

Mike M. Ellsbury

Northern Grain Insect Research Lab, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Brookings, South Dakota, U.S.A.

Abstract

Much of the knowledge about how soil-dwelling insects survive cold soil temperature has come from scientific studies done in arctic or alpine environments under extreme conditions. The basic concepts arising from these studies have been summarized in this entry. It is evident that insects have adapted to cold soil environments through a variety of mechanisms and that no single strategy suffices for survival in cold environments for all insects. The survival of corn rootworm eggs illustrates how some of this knowledge can be applied to an insect pest in a temperate agricultural setting.

INTRODUCTION

Insects that inhabit soil in regions where winter temperatures fall below freezing have necessarily evolved behavioral and physiological mechanisms for surviving and developing in seasonally cold environments. Reviews of literature relating to the physiological, ecological, and behavioral adaptations that allow insects to survive cold temperature appear in the work of Baust et al.,^[1] Cannon and Block,^[2] Block,^[3] and Danks.^[4] A review by Danks^[5] considers relationships between dehydration and cold hardiness in dormant insects. Danks et al.^[6] and Block^[7] have also compiled concise glossaries of scientific terms associated with cold hardiness in insects.

BEHAVIORAL ADAPTATION

Behavioral mechanisms for avoidance of low temperatures may entail movement of freezing-susceptible overwintering stages deeper into the soil or to sites protected from cold temperatures.^[8,9] Snow cover has an insulating effect that mediates winter soil temperatures, producing nearly isothermal soil temperature regimes when early snow cover occurs.^[9,10] Where snow cover is sparse or lacking soil temperature more closely follows extremes of air temperature^[11] and cold-hardiness adaptation becomes more important for overwinter survival of soil-dwelling insects. This is particularly true of soil-dwelling invertebrates of arctic regions that cannot avoid exposure to cold temperature and thus have necessarily evolved cold-hardiness traits and diapause capability that enable them to survive during exposure to subfreezing temperature. Where short warm seasons occur, modified, sometimes very prolonged, life cycles extending over more than one overwinter season are found in insects of cold environments.^[3,6,9]

PHYSIOLOGICAL ADAPTATION

Cold hardiness involves physiological and metabolic adaptations that may not always be concomitant with a depressed diapause metabolism. Diapause has been defined as hormonally controlled metabolic dormancy that occurs during a specific stage in the life cycle of an insect.^[12–14] Thus, cold hardiness may occur independent of diapause but often is an integral component of the diapause trait, and diapause expression may improve the cold-hardiness capability of the insect.^[15]

FREEZE TOLERANCE VS. FREEZE SUSCEPTIBILITY

Cold-hardy insects have been characterized into two groups: those that are tolerant to freezing and those that are susceptible to freezing.^[8,16,17] The first of these, insects that are freeze tolerant, survive ice formation in body tissues but avoid damage to intracellular components because ice formation is usually confined to extracellular fluids. Protective mechanisms for freezing resistance include elevated solute levels, presence of nucleating agents, and accumulation of cryoprotectants in body fluids. The second broad category includes insects capable of undergoing supercooling without freezing of body fluids at temperatures that are below the true freezing point or melting point.^[6] Insects that have the ability to supercool are considered freezing susceptible because they avoid freezing damage to body tissues only at temperatures above the supercooling point. Below the supercooling point, ice formation in body tissues results in death. These relationships are summarized in Fig. 1. It should, however, be noted that a strict dichotomous categorization of the cold-hardy stages of insects as either freeze tolerant or freeze susceptible may be an oversimplification.^[7] Kostal and Havelka^[18] observe that in soil

Fig. 1 Generalized diagram showing insect responses to cold temperature. Heavy line indicates insect body temperature and shaded area is a zone where ice nucleation occurs.

Source: From Danks, Kukal, et al.^[6]

environments where freezing events occur unpredictably, overwintering stages of some insects display both freeze susceptibility (supercooling) and freeze tolerance. In many insects, particularly those of more temperate environments, cold hardiness is associated with ability to survive low temperature during chilling events but is not necessarily associated with extremes of subfreezing temperature.

The capacity of insects to supercool may be enhanced by acclimation at low temperatures, still above the supercooling point, prior to exposure to subfreezing temperatures. However, where acclimation does not occur, exposure to rapidly falling temperature, even for short durations, may induce cold shock or direct chilling injury. Cold shock is defined as stress associated with short duration or rapid exposure to low, but non-freezing temperature.^[19] The rate of cooling is more significant in producing cold shock injury than are the duration or the level of low temperature attained during the chilling event. Insects subjected to cold shock sustain injury at temperatures well above the supercooling point. The mechanism of injury caused during cold shock probably involves changes in structure of lipids associated with membranes or thermoelastic stress induced by rapidly falling temperature.^[19–21]

Lee et al.,^[22] described a process for rapid cold hardening of insects during exposure to low temperature that would otherwise result in cold shock. The phenomenon has been associated with glycerol accumulation^[23] and production of stress proteins similar to those produced in response to heat shock.^[24] The rapid cold hardening phenomenon was observed in non-overwintering stages and probably provides insects with means to avoid direct chilling injury during rapid exposure to low temperatures above the supercooling point. This adaptation could be particularly

important for soil-dwelling organisms of temperate regions that may be exposed to rapid freeze–thaw events during the autumn or spring. The association of heat-shock protein production with cold hardiness suggests similarities between rapid cold hardening and insect response to heat stress by production of heat-shock proteins.

Mortality during cold exposure may result from dehydration during the freezing process, even in insects that are freeze tolerant.^[8] Indeed, Ring and Danks^[25] suggested that physiological and behavioral traits considered adaptive to cold hardiness may also be adaptive to survival in dry winter conditions. Block^[26] concluded that resistance to desiccation may be considered preadaptive to cold hardiness in terrestrial arthropods.

CORN ROOTWORMS

The ability of certain *Diabrotica* beetle species (Coleoptera: Chrysomelidae) to survive winter desiccation in tropical climates may have preadapted them for survival in more northern climates. Pest *Diabrotica*, of the corn rootworm complex, are thought to have expanded their range northward from tropical regions into areas of more temperate climate concomitantly with the agricultural development of corn, *Zea mays* L., as a primary host plant. Western corn rootworms, *Diabrotica virgifera virgifera* LeConte, considered by Krysan^[27] to be of tropical origin, survive cold winter conditions in temperate regions as a diapausing egg stage in the soil. The diapause mechanism that enabled survival of eggs during seasonal desiccation in the tropics also probably preadapted the soil-dwelling egg stage of this insect to survive in frozen soils.^[28] A closely related subspecies, the Mexican corn rootworm, *D. virgifera zea*, also overwinters as a diapausing egg stage in the soil but is adapted to survive dry winters in more southern climates.^[29] These observations are consistent with the suggestion by Block^[7] that insects tolerant of desiccation also are probably preadapted for survival of cold temperatures.

In the northern Great Plains, the *Diabrotica* pest complex consists of two species, the western corn rootworm, *D. virgifera virgifera*, and the northern corn rootworm, *D. barberi*. Because both species overwinter as eggs in the soil, the occurrence of an economic infestation during the following growing season depends in part on the overwintering survival of the egg. Chiang,^[30] Chiang et al.,^[31] Calkins and Kirk,^[32] and Gustin^[33,34] determined that winter soil temperatures reach levels low enough to cause mortality in overwintering western and northern corn rootworm eggs in the northern Great Plains. Nonetheless, a significant proportion of eggs laid each fall frequently survive winter conditions in corn-growing areas of North America to produce economic infestations of these insects each year.

Ellsbury et al.^[35,36] have shown that adult emergence patterns of both rootworm species have highly variable

spatial distributions in the field. These distributions are probably the result of behavioral and mortality factors operating on eggs in the soil at two points in the seasonal life cycle of these insects. Firstly, ovipositional patterns may vary spatially in three dimensions with adult response to corn maturity, and soil texture and moisture conditions. Secondly, distributions of eggs in the soil may change from those that exist just after the oviposition period because of differential overwinter mortality. The influences of fall tillage, soil characteristics, snow cover, and soil temperature are known to mediate egg mortality, but the interactions between these factors that produce spatial and temporal variation in surviving rootworm populations are poorly understood.

The effect of low winter soil temperature on corn rootworm eggs has been the subject of intense study. Some early research on this subject was driven by the need for laboratory rearing of large quantities of postdiapause eggs for artificial infestation and thus was focused on the biology of egg diapause, temperature limits for development, and optimal chilling conditions for storage of eggs. Much research effort has been directed toward determining developmental thresholds and diapause requirements of rootworms in cold temperature environments; little information is available about cold hardiness and the actual cold hardening mechanism of the overwintering egg stage, nor is it known whether corn rootworm eggs can be considered freeze tolerant or freeze susceptible.

CONCLUSION

Much of the knowledge about how soil-dwelling insects survive cold soil temperature has come from scientific studies done in arctic or alpine environments under extreme conditions. The basic concepts arising from these studies have been summarized in this contribution. It is evident that insects have adapted to cold soil environments through a variety of mechanisms and that no single strategy suffices for survival in cold environments for all insects. The discussion of survival of corn rootworm eggs was intended to illustrate how some of this knowledge can be applied to an insect pest in a temperate agricultural setting. There are of course other soil-dwelling insects that overwinter in various life stages in both agricultural and natural settings that, for want of space, could not be considered here. However, it can be said that these basic concepts and references provided herein should serve as a point of departure for the reader wishing to undertake more in-depth study or research on the survival of insects in frozen soil environments.

Integrated Nutrient Management

Bal Ram Singh

Abstract

Integrated nutrient management (INM) balances plant nutrient supply from both inorganic and organic sources to an optimum level for sustaining the desired crop yields as well as addresses the society's environmental concerns. The organic resources that otherwise considered waste and potential environmental polluters such as biosolids and industrial by-products are utilized as plant nutrient source complemented by mineral and synthetic fertilizers and biologically fixed nitrogen in INM system. Besides plant nutrient supply, organic component of INM also contributes to the maintenance or buildup of soil organic matter, which is critical for physical, chemical, and biological functions of soil. The INM is most relevant to agroecosystems where there is a large nutrient imbalance, and continuous depletion of organic matter and environmental concerns for disposal of organic wastes and by-products occur. Caution is required, however, to avoid accumulation of toxic elements and pesticides. In practice, INM considers the following: 1) availability of on-farm and off-farm resources; 2) yield target based on resource availability; 3) nutrient requirement to achieve desired yield; 4) integration of mineral and organic fertilizers; 5) time and method of fertilizer application; 6) efficient soil and water conservation measures; and 7) sustaining physical, chemical, and biological fertility of soils.

INTRODUCTION

Integrated nutrient management (INM) implies the maintenance or adjustment of soil fertility and of plant nutrient supply to an optimum level for sustaining the desired crop productivity on one hand and to minimize nutrient losses to the environment on the other. It is achieved through efficient management of all nutrient sources. Nutrient sources to a plant growing on a soil include soil minerals and decomposing soil organic matter (SOM), mineral and synthetic fertilizers, animal manures and composts, by-products and wastes, plant residue, and biological nitrogen fixation (BNF). Irrigation water and aerial deposition generally are minor nutrient sources. The INM is, however, not a matter of conserving soil nutrient alone, but rather it combines organic and mineral methods of soil fertility management with physical and biological measures of soil and water conservation. It integrates technologies that are site specific to agronomic and socioeconomic conditions to redress nutrient imbalances and organic matter deterioration.^[1]

The cropping system, rather than a single crop, and farming system, rather than an individual field, are the focus of an INM approach for developing the practices for the main agroecological region of a country and for the various categories of farms. The INM identifies the best associations of various types of plant nutrients in different

fields for a balanced plant nutrient and plant yield, while sustaining soil fertility and controlling nutrient losses.^[2] The farming system approach helps the farmer in the choice of the most adapted INM technologies for increasing farm production and labor productivity. It is envisaged that locally available materials of plant or animal origin as by-products of agricultural activities be used or, where such materials are not available, *in situ* production of organics, such as fast-growing leguminous shrubs or green manure crops, be practiced. The latter practice will bring atmospheric nitrogen (N) into the system, and occasionally through their deep roots, nutrients leached beyond root zones and subsoil mineralized nutrients are brought to the surface layer for use by annual crops.^[2]

The INM must essentially look into three main challenges: 1) judicious use of mineral fertilizers; 2) maximize use of organic materials; and 3) minimize negative environmental impacts. The overall strategy of INM, for determining the yield-based nutrient requirements, involves several steps, for example: 1) availability of on-farm and off-farm resources; 2) yield target based on resource availability; 3) nutrient requirement to achieve desired yield; 4) integration of mineral and organic fertilizers; 5) time and method of fertilizer application; 6) efficient soil and water conservation measures; and (7) sustaining physical, chemical, and biological fertility of soils.^[1]

Fig. 1 Determining the yield-based nutrient requirement through a judicious combination of chemical and biofertilizers.

COMPONENTS OF INM

The main components of an INM system are shown in Fig. 1. The figure shows a judicious integration of mineral, synthetic, and biofertilizers, both organic materials and BNF.

Mineral and Synthetic Fertilizers

Fertilizers have played an important role in increasing the food supply all over the world. It is estimated that about 50% of the annual global food harvest comes from the application of mineral N fertilizer alone.^[3] In most regions of the world, increase in food production since 1980s has resulted mainly from raising yields per unit of land through increased mineral fertilizer use. The major exceptions are Africa and the Cerrado of Brazil, where most of the growth in production is caused by expansion of the cultivated area.^[3] Since 1960s, grain production in India has gone hand in hand with fertilizer consumption. The grain production increased from 52 MT in 1950/1951 to about 200 MT in 1998, while the increase in fertilizer nitrogen, phosphorus, and potassium (NPK) consumption during the same period increased from about 0.07 to 14.3 MT.^[4] It must, however, be emphasized that, along with fertilizer consumption, use of high-yielding varieties and increased irrigation facilities have played the key role in this spectacular rise in grain production.

Fertilizer consumption (N, P, and K) in the world and South Asia increased by several folds between 1975 and 2000 (Table 1). The increase in N use was only twofold on a worldwide basis, while it was about sixfold in South Asia. The corresponding increases in P and K use in South Asia were about eight- and sixfold, respectively. The average application rates of mineral fertilizers in different

development regions of the world have also increased greatly, while the rate applied in Sub-Saharan African (SSA) countries has continued to be very low. For example, the weighted average of plant nutrients in East Asia and Pacific increased from 36.4 kg ha⁻¹ in 1970 to 190.3 kg ha⁻¹ in 1990. The corresponding rates in Latin America and Caribbean were 20.3 and 46.8 kg ha⁻¹, respectively, while these rates in SSA countries remained at 3.3 and 8.9 kg ha⁻¹.^[6] This has resulted in continuous decrease in per capita food production in Africa from 1980 to 1995 in contrast to sustained increase in Asia and Latin America. Assuming the base line of 1979–1981 at 100, per capita food production in Africa decreased to 93 in 1995, whereas the production during the same period in Asia and Latin America increased to 128 and 112, respectively.^[7]

Mineral fertilizers supply three major nutrients, and some management aspects of these nutrients are discussed below.

Nitrogen

Crop response to N is universal and to produce 1 t of grain, cereal crops require 15–30 kg N.^[8] Since food demands in developing countries are increasing, fertilizer N will be the most needed nutrient. N is difficult to retain in soils, and it is subjected to leaching to underground layers. Estimates of 40–50% of the mineralized N being lost under high rainfall environments of West Africa have been reported.^[9] However, leaching of mineralized NO₃-N is slower than that of NO₃-N applied as fertilizer, mainly due to time taken for the NO₃-N to diffuse to the larger pores and channels through which water drains preferentially.^[10] N is also lost to the atmosphere through denitrification and ammonium volatilization, and thus, its fertilizer use efficiency is low. The average recovery of N by rice crop in the farmer's fields in five countries was found to be only 30%,^[8] while it was 40–60% in other crops.^[4] In a long-term experiment (22 years) in India, it was found that N recovery was 17% in maize and 32% in wheat with application of N alone, but the recovery was almost doubled (33% in maize and 65% in wheat) when P and K along with N were applied.^[11] The later treatment also resulted in buildup of organic carbon (C) in the soil. Singh and Swarup^[12] also

made similar observations based on the results from several long-term experiments from different parts of India. They also found that continuous use of N alone resulted in the greatest decline in yield at all centers, indicating that other major and micronutrients were becoming limiting factors and adequate response to N could not be obtained unless the yield-limiting factors were remedied.

Phosphorus

P deficiency is considered as the main biophysical constraint for food production in humid and subhumid tropics. P dynamics in soils is complex, as it involves both chemical and biological processes and the long-term effects of sorption processes.^[13] The P supply through organic materials (crop residue and manures) is often inadequate to meet crop requirement, and thus, P fertilizer is necessary to overcome P depletion. Recovery of P is even lower than N, only 10–20%. However, unlike N, applied P is not lost from the soil except through soil erosion and gets accumulated into its reserves. In the high P-sorbing soils of Cerrado, Brazil, large application of P can replenish P, and the residual effects of P can last for 5–10 years.^[14] These corrective applications along with subsequent maintenance application and sound agronomic practices have proved very successful in this region.^[14]

High-reactive phosphate rock (PR) can be used in acid soils with similar effectiveness as superphosphate, but seldom in soils with pH above 6.2.^[15,16] High to medium reactive (>15 g citrate soluble P kg⁻¹), sedimentary PR deposits found in several African countries have been found suitable for direct application, while others are effective when partially acidulated, applied in combination with soluble P fertilizers or mixed with organic inputs.^[16] Ground PR, even on neutral or alkaline soils in India, has proved beneficial with the help of P-solubilizing organisms and organic residues.^[4] On-farm research from western Kenya shows the potential of combining organic and inorganic sources of P in moderately P-sorbing soil.^[13] They found that the application of *Tithonia* without P doubled maize yields in comparison to equivalent N rate as urea. The combination of *Tithonia* biomass with 250 kg P ha⁻¹ as Minjingu PR increased maize yields fivefold. The benefit of *Tithonia* was partially attributed to 60 kg K ha⁻¹ with the plant material. The integration of locally available organic resources with P fertilizer may be the key to increasing and sustaining levels of P on smallholder African farms.

Potassium

Unlike N and P, most K is retained in straw; thus, if crop residue is returned to the soil, the bulk of the depleted K can be replenished. However, soils such as Oxisols and Ultisols are too deficient in reserve K, and profitable yields cannot be obtained without K application. Singh and Goma^[17] reported maize response to K application on an Oxisol

3 years after the start of a long-term experiment in Zambia. With continuous mining of K with high-yielding varieties, several areas in the Indo-Gangetic alluvium have become deficient and good response to K application is reported.^[4] The results indicate that increased intensity of cropping will lead to a greater need for K input.

Biofertilizers

Although the judicious use of mineral fertilizer can play a critical role in preventing resource degradation that results from nutrient mining and from the exploitation of fragile lands or the clearing of habitat-rich forests, negative environmental impacts of mineral fertilizer application remain a matter of global concern. Therefore, mineral fertilizer application integrated with biofertilizers (organic fertilizers, crop residues, manures and wastes, and BNF) has received greater attention in sustaining crop productivity and replenishing soil fertility in many countries.

The rate of supply of nutrients from biofertilizers is generally slower than that from mineral and synthetic fertilizers, and thus, the former are essentially slow-release fertilizers. Nutrients are slowly released from biofertilizers through the microbial decomposition of organic materials. Therefore, the combined use of mineral fertilizers (fast nutrient release) with biofertilizers (slow nutrient release) in an INM system is capable of synchronizing nutrient supply with nutrient needs throughout crop growth, thereby maximizing nutrient use and minimizing nutrient loss and environmental pollution. Farmers make limited use of this concept, primarily because there are no routine techniques available to rapidly assess the nutrient availability from biofertilizers and then adjust the mineral fertilizer rates accordingly.

Biologically fixed nitrogen, crop residue, organic manures and composts, and sewage sludge as biofertilizers are discussed in the following section.

BNF, Leguminous Crop Rotations, Agroforestry, etc.

The major sources of BNF are the legume–*Rhizobium* symbiosis and Cyanophyta (blue-green algae), which fix atmospheric N into organic forms in soil. Non-symbiotic N fixers (*Azospirillum* and *Azotobacter*) and others such as *Azolla* and *Actinorrhizae* (*Frankia*) make a small, but significant, contribution to N cycling in natural ecosystems. On a global scale, it is estimated that BNF provided about 140 Mt of N compared with 108 Mt of fertilizer N in 2011, thus emphasizing the contribution of BNF to global N cycle. The legume–*Rhizobium* symbiosis fixes atmospheric N from 35 to 300 kg N ha⁻¹ in a growing season and leaves substantial amount of N (20–150 kg N ha⁻¹) for the following crop.^[18]

Agroforestry that includes legume trees provides another venue for BNF benefits, in addition to recycling

of mineral nutrients brought up from below the root zone of annual crops, organic amendments with PR to enhance P availability.^[18]

Most of the biological N fixed is present in organic form and therefore it must be mineralized before the following crop can utilize it. It thus has the potential to complement the crop nutrient needs with readily available nutrients such as from mineral and synthetic fertilizers in an INM system. Legume green manuring and incorporation of catch crops could also be used toward that purpose, although limitation of land and water for this practice and cheaper N fertilizers restricts its widespread use.

Biosolids, Manures, Composts, and By-Products (e.g., Crop Residue and Sewage Sludge)

Manures and composts provide N, P, and K (5–35 kg N t⁻¹, 1–10 kg P t⁻¹, and 5–35 kg K t⁻¹) not only to crops but also to other nutrients including micronutrients, as well as affect physical, chemical, and biological properties of soil. In an integrated crop–animal farming system, nutrient contribution from applied manures and composts becomes significant and synchronizes nutrient supply to crops when complemented by mineral and synthetic fertilizers. For example, Rao et al.^[19] showed that 120 kg N ha⁻¹ fertilizer application provided similar wheat yields to that obtained with 60 kg N ha⁻¹ fertilizer plus 4 t ha⁻¹ farmyard manure (FYM); besides, this quantity of manure also provided grain yield response equivalent of 9 kg P ha⁻¹ (Table 2). Since N release from manure occurs over a number of seasons (20–40% in the first season and 10–20% in subsequent seasons), the cumulative effect of manure application is much greater than that assessed in a single season. Furthermore, since N in compost is more stabilized than in manure, the rate of N release from the former would be slower.

Because P contained in PR is less available than that in superphosphate, its availability is enhanced when it is added in manure and organic wastes and composted together (phospho-compost) before its application to the

field. Bhardwaj^[20] reported that the grain yield increase following 25 kg P ha⁻¹ application from phospho-compost was essentially similar to that from superphosphate; this also avoids the acidifying effect of the latter to the soil.

In low-input farming systems, return of crop residues provides significant quantities of N, P, K, and calcium (Ca); in the aboveground crop biomass, the latter two exceed more than 60% of the total nutrient uptake. This becomes especially critical in some tropical Ultisols, Oxisols, and Alfisols, with low exchangeable Ca and K in these soils. For example, Sanchez and Benites^[21] reported that the retention of rice and cowpea crop residues returned to an Ultisol, 94% Ca and 89% K that were accumulated by the crops. Addition of legume residues of *Sesbania*, *Gliricidia*, and *Leucaena* and supplementation with fertilizers is an important component of INM system, especially in low-input farming systems.

Urbanization has necessitated the need for safe and economic disposal of the sewage sludge. Application of the sewage sludge to soil ensures the recycling of nutrients and organic matter and benefits plant production. Digested sewage sludge contains, on average, 7.5 kg N t⁻¹ and 3.9 kg P t⁻¹;^[22] the N and P contents of the sewage sludge lie within the range of manures and composts, almost 40% of N and 50% of P being available to crops in the first year of application to soil. Significant ammonia volatilization could occur from surface application of sludge, especially liquid sludge and animal slurries. Because the sewage sludge contains relatively more P than N required by crops, the application rates based on P requirements of the crops require supplementary N applications. Thus, it would require an INM approach to balance N and P needs of the crops.

ENVIRONMENTAL CONCERNS OF INM

Nutrient Losses

Removal of nutrients from the agricultural systems is through harvest products, soil erosion and leaching, and gaseous losses. Stoervagel and Smaling^[23] estimated the losses of 10 kg N, 1.7 kg P, and 8.3 kg K ha⁻¹ for soils in SSA and suggested that nutrient mining is responsible for declining soil fertility in this part of the world. Much of N losses occur through leaching, but the quantities of N lost in leaching depend on the amount of N fertilizer applied, soil type, crop grown, and climatic conditions. The losses can range from 0 to >100 kg N ha⁻¹ yr⁻¹ and they are more in soils with large rainfall intensities and low-storage capacity. The INM through organic and inorganic input of N can also minimize the leaching losses by improving soil chemical and physical properties. The accumulation of nitrate in soil was less under balanced use of nutrient application, and the use of FYM in conjunction with 100% NPK marginally increased the nitrate content in the surface layer.^[11] Most of P is lost through crop removal and surface erosion. P is

Table 2 Effects of manure and fertilizer applications on wheat yields.

	Wheat grain yield (t ha ⁻¹)				
	Fertilizer N (kg N ha ⁻¹)			Fertilizer P (kg P ha ⁻¹)	
Manure (t ha ⁻¹)	0	60	120	0	11
0	1.65	2.58	2.86	1.59	2.71
4	1.98	2.90	3.90	2.49	3.28
8	2.36	3.29	3.80	3.18	3.62

Source: Adapted from Rao, Singh, et al.^[19] ©1998 Indian Institute of Soil Science.

generally the limiting nutrient for algae growth and phosphate fertilizers applied to nutrient-deficient, leaching, and sandy soils were the main sources of P in these ecosystems of Australia.^[23] Neither fixed nor exchangeable K is very mobile in soils containing silicate minerals. However, Oxisols and Ultisols have limited capacity to maintain adequate K. Leaching losses in tropical soils are reported to vary from 52 to 165 kg K ha⁻¹ yr⁻¹, and they are especially higher under slash and burn.^[24] The INM with organic matter input is important in these soils to increase their cation-exchange capacity and nutrient retention capacity.

Toxic Accumulation

Commercial P fertilizers can be a major source of metal addition, especially cadmium (Cd), to agricultural soils.^[25] Also, urban sewage sludge and certain animal waste products, for example, pig manure, may also contain high amounts of metals.^[22] Repeated application of such wastes is reported to increase crop uptake of metals.^[26] Some accumulation of Cd in soils from fertilized fields, especially in Europe and North America, has been observed. The Cd content of some crops may reach to levels that could be harmful for human food and animal feed. Hence regulatory limits for food, the so-called “maximum permissible concentrations,” have been worked out in some countries. Research efforts are being made to reduce the Cd content of the fertilizer produced.

Soil Fertility Degradation/Improvement

The rapid loss of SOM of the topsoil after clearing of the natural vegetation or under continuous cultivation is a common phenomenon in the tropics and subtropics.^[27] In Zambia, the SOM content of an Oxisol decreased at the rate of 1.6 Mg ha⁻¹ yr⁻¹ in a long-term experiment.^[17] At Kabete, Kenya, the application of NP fertilizer maintained the soil organic C after 16 years of cultivation, but the content of organic C declined continuously in unfertilized plots, whereas the combined use of NP, FYM, and crop residue increased organic C and crop yields.^[28] Similarly, the long-term studies in subtropics^[11] and temperate regions^[5,29,30] have shown that organic matter of soil can be maintained or raised modestly by proper fertilization and especially by organic manures and crop residue management.

CONCLUSIONS AND RESEARCH PERSPECTIVES

Continual fertility depletion in developing countries and excess mineral nutrient applications to soils in many temperate, developed countries have led to nutrient and fertility imbalances in terms of nutrient depletion^[31] and imbalance, hence low-crop production on one hand, with excess

nutrients, soil, water, and air pollution on the other. INM is seen as the most useful approach to overcoming such problems in which adequate nutrient supply, in synchrony with crop demands, is provided within a framework of improved land and soil management practices. Implementation of INM systems could not only increase crop production per unit area of land to meet the demands of an increasing population but also improve the environment by utilizing nutrients in organic resources available to the community. Improved understanding of nutrient availability from these resources and fate of nutrients in an integrated (soil–plant–water–air) system is required as they impinge on the soil’s chemical, biological, and physical functions for sustainable production.

Increasing transport of nutrients from agricultural lands to settled and expanding urban areas through food chain has led to soil nutrient depletion and imbalance for crop productivity on one hand and excessive concentration and problematic disposal of nutrients through biosolids, food, and industrial wastes on the other hand. It is imperative that this cycle is reversed, and in this process, biofertilizers are produced and utilized. This requires research to recover nutrients from biosolids and wastes and to remove toxic elements and pesticides from biosolids and transport economically to croplands where these are used in INM system for crop productivity and sustainable intensification of agriculture.^[32]

Abstract

The integrated nutrient management (INM) strategy involves meeting a crop's nutritional requirement to achieve the desired yield through judicious use of inorganic fertilizers, biofertilizers, biosolids, biological nitrogen fixation, and other nutrient cycling mechanisms that enhance nutrient use efficiency and optimize the use of the most limited or non-renewable resources. This entry outlines the basic principle of INM in the context of resource-poor farmers of Asia.

INTRODUCTION

The world population of 6 billion in 2000, increasing at the rate of 1.8%/yr, is expected to reach 8 billion by the year 2025 and 9.4 billion by 2050.^[1–3] Most of the population increase will occur in the developing countries. By 2050, the population would have increased by another 575 million in India, 300 million in China, 200 million in Nigeria, 200 million in Pakistan, and 140 million in Ethiopia.^[4] About 780 million people are already food insecure in the developing countries. The Asian farmers feed nearly 60% of the world population from only 25% of the world's land available for agriculture. The global demand for food may double over the period 1990–2030, with an increase of 2.5 to 3 times in the developing countries.

The green revolution, which started in the 1970s, was perceived by some as a near miracle preventing starvation in many Asian countries. It was brought about by increased yields of irrigated rice (*Oryza sativa*) and wheat (*Triticum aestivum*) grown on fertile soils with intensive use of fertilizers. However, gains in agricultural production are not being sustained where inputs are insufficient or imbalanced, soil fertility is declining, and other soil degradative processes are severe. Thus, food insecurity in the Asian region is once again a matter of grave concern. The threat to food security in Asia is caused by the degradation of hitherto fertile soils, especially because of the depletion of soil organic matter (SOM) content and associated plant nutrients. There is little scope for an increase in arable area, which is likely to decrease because of urbanization and soil degradation. Thus, a prerequisite for increasing food production is to develop, fine tune, and implement soil/crop management practices, which

enhance and maintain the SOM content and plant nutrient reserves at appropriate levels. Adopting a strategy of integrated nutrient management (INM) can increase nutrient use efficiencies, strengthen nutrient cycling, and increase and sustain food production.

SUSTAINABLE AGRICULTURE

Sustainable agriculture involves enhancing and sustaining agricultural production while preserving or improving soil fertility, maintaining a clean environment, and protecting or regenerating biological diversity and ecosystem health. The Technical Advisory Committee of the Consultative Group on International Agricultural Research defined sustainable agriculture as the “successful management of resources for agriculture to satisfy changing human needs while maintaining or enhancing the quality of the environment and conserving natural resources.”^[5] Traditional farming has been basically a sustainable agriculture, but at a low level of output supporting subsistence living. The transition from traditional to intensive agriculture is necessitated by the increase in global food demand and a widespread problem of soil and environmental degradation.

FERTILIZER MANAGEMENT

The use of plant nutrients per unit of net cropped area is more in Asia (129 kg/ha) as compared to that in the rest of the world (90 kg/ha). However, the ratio of nitrogen (N)/phosphorus (P)/potassium (K) use is quite balanced for the world (3.8:1.5:1), but not so for the Asian region (7.9:2.7:1).^[6] The wide ratio is not conducive to

sustained agricultural production and needs to be altered to achieve the desired ratio of about 4:2:1. The fertilizer consumption of China and India is about 70% of the total fertilizer consumption in Asia,^[6] and approximately 60% of the fertilizers consumed in Asia are used on rice.^[7] The increase in agricultural production in China during 1978–1995 was 32% by fertilizer use, 28% by irrigation, 17% by improved seed, 13% by machinery, and 6% by other factors.^[8] Furthermore, the use of chemical fertilizers will continue to play an important role in augmenting global food production. To enhance the efficiency of use and maximize the benefits, fertilizers must be applied at the right amount, placed in the root zone at the right time, and applied in the right formulation and combination. High crop yields deplete the nutrient reserves^[9] and, unless replenished judiciously and regularly, can lead to nutrient imbalance in soil. Indeed, crop yields in intensively cultivated irrigated areas of northwestern India are either stagnating or declining in the post-green-revolution period, because of the degree of nutrient imbalance, severity of soil degradation, and intensity of cropping. Nutrient removal by different crops for a definite yield target is presented in Table 1.

Nitrogen

Because of the large requirement of N for vigorous growth of the plant, crop response to N application is universal. N represents approximately 70% of the total fertilizer nutrients (N + P + K) consumed in Asia.^[10] N requirement for one metric ton (Mg) of cereal grains is 15–30 kg.^[11] As cereal grains are a staple food group

in Asia, an earnest effort has been made for increasing cereal production, thereby leading to increased demand for fertilizer N. This trend is likely to continue in future, and fertilizer N will continue to be the most wanted nutrient.

Rice crop on an average needs about 20 kg N to produce one Mg of grain yield.^[12] Thus, high yielding varieties producing 5 Mg of grain yield need 100 kg N from both soil and fertilizer sources. If grain yield without fertilizer (native soil N) is about 2.5 Mg/ha, it requires about 50 kg N/ha through fertilizer use. Assuming fertilizer N recovery of 40%, it involves applying 125 kg N/ha through fertilizer use for obtaining a target yield of 5 Mg/ha. The efficiency of applied N is usually low and ranges from 25% to 45% in rice and 50% to 70% in upland crops.^[13] In general, a 1% increase in the recovery rate of N will normally result in an economy of 0.15 million Mg of urea per year in India, which would be equivalent to one million Mg of food grains in terms of additional crop production.^[14]

Efficiency of fertilizer N is also dependent on the form of N applied and the ecosystem in which they are used. Meelu and Morris^[15] reported that amide (urea) and ammoniacal sources (ammonium sulfate) of N are superior to nitrate (calcium ammonium nitrate) for rice. But in case of hybrid rice, there are contrary reports from China. The superiority of ammoniacal source, however, is because of its stability under flooded conditions compared to nitrate, which is highly unstable and lost through leaching and denitrification. The reported superiority of nitrate for hybrid rice is attributed to the physiological/genetic differences between the inbreds and hybrids.^[16]

Phosphorus

Asia consumes about 30% of the world's P fertilizer,^[10] and China and India are the main P users in Asia. In contrast to N, only 2–5 kg P is removed per Mg of cereal produced, and P use efficiency by single crop rarely exceeds 15–20% of added P. Because of its relative immobility, applied P is fixed in the soil and may be absorbed by subsequent crops. The magnitude of the residual effect depends on the rate and kind of P fertilizer and cropping and management practices and largely on soil type. Thus, P fertilizers applied to a single crop often can meet the P requirement of subsequent crop/crops in a cropping system. Gill and Meelu^[17] reported that when P is applied to wheat, at the recommended rate, the following rice crop can be grown on residual P. However, when P is applied only to rice, grain yield of wheat is considerably lowered. De Datta, Buresh, and Mamaril^[7] also reported that P use efficiency can be greatly improved by the choice of the crop to be fertilized in a sequence. The fertilization of a single crop in a sequence can lead to net negative P balance in the soil. Regular monitoring of nutrient balance,

Table 1 Nutrient requirement of principle crops.

Crop	Scientific name	Yield (Mg/ha)	Nutrients (kg/Mg of yield)		
			N	P ₂ O ₅	K ₂ O
Wheat	<i>Triticum aestivum</i>	5.0	31	5	37
Rice	<i>Oryza sativa</i>	6.3	15	4	24
Corn	<i>Zea mays</i>	2.7	42	17	40
Sorghum	<i>Sorghum bicolor</i>	1.1	47	16	8
Millet	<i>Pennisetum typhoides</i>	0.6	50	18	170
Sugarcane	<i>Sachharum offinarum</i>	87.1	1.4	1	2.6
Potato (tubers)	<i>Solanum tuberosum</i>	17.6	5	2	8
Barley	<i>Hordeum vulgare</i>	2.5	22	12	60
Groundnut	<i>Erychus hypogea</i>	1.9	41	11	24
Mustard	<i>Brassica campestris</i>	0.7	31	16	40

therefore, is important for greater precision in scheduling fertilizer use.

The use efficiency of P can vary widely depending on soil type, crop, and the source of fertilizer. For short duration and winter crops water-soluble P (WSP) sources and nitrophosphates with 70% WSP have higher efficiency than water-insoluble or less water-soluble sources.^[18] For long duration and summer crops, the differences among sources with regard to P use efficiency are minimal. Method of P application plays an important role in P use efficiency, and about 50% of fertilizer can be saved by placement in row crops as compared with the broadcast method,^[19] while the reverse may be true for rice.

The dynamics of P in upland soils is markedly different from that of lowland soils. Available P increases during the flooding phase and decreases during the drying phase. In general, wetland rice is less responsive than all dryland crops grown on the same soil. Soil P continues to be an “enigma” to soil scientists, and INM strategies can help in solving some of the problems of soil P management.

Potassium

Asia consumes only 15% of the world's K fertilizer,^[10] and China and India are the main K-fertilizer-consuming countries in Asia. The K use efficiency is about 80%. The neglect of K application is evident from the highly imbalanced fertilizer consumption ratio in most the developing countries. Unlike N and P, response to K application is small on soils with illitic clay minerals. The response to K is usually observed in acidic and sandy soils during the summer season in the high rainfall areas where it is prone to leaching. The response of corn (*Zea mays*) and rice to K is more than that of wheat.^[20] Production of one Mg of rice grains requires 17–25 kg K/ha.^[21,22] Thus, continuous appraisal of the crop response to K in relation to soil test is important.

Other Nutrients

Among the secondary nutrients, sulfur deficiency is widespread with the continuous use of high analysis sulfur (S)-free fertilizers. The S deficiency usually occurs in soils of humid regions, which are highly oxidized, sandy, and low in total S and SOM contents. Similarly, zinc deficiency is another disorder limiting the yield of crops, especially of rice. Other micronutrient deficiencies are also appearing because of low use of organic manures and increased use of high analysis fertilizers.

INTEGRATED NUTRIENT MANAGEMENT

The multilocal testing by All India Co-ordinated Rice Improvement Project has shown a 50% decline in

the response of rice to fertilizer from 15–16 kg grain/kg NPK nutrients applied in the 1960s and 1970s to 7–8 kg grain/kg NPK applied in the 1990s.^[23] Thus, there is a strong need to assess both balanced fertilization and integrated plant nutrient management, which are not synonymous. The balanced fertilization implies balancing the ratio of applied nutrients to that of the nutrient requirements of the crop, and the INM implies combining organic and mineral methods of soil fertility management to reduce risks of nutrient imbalances and depletion of SOM reserves. The SOM is a biological buffer, which plays an important role in maintaining the balanced supply of available nutrients for plant growth. The higher SOM content reflects higher soil productivity.^[24] Therefore, application and management of biosolids as fertilizers are viable options to improve plant growth. Soils with low SOM content lose their buffering capacity and productivity and have low fertilizer use efficiency. In areas of intensive cropping, an increased level and better quality of SOM can contribute significantly to high productivity.^[25] Organic fertilizers vary widely in terms of their nutrient contents (Table 2), depending on the biosolids and their constituents.^[26]

The data from long-term experiments under diversified agroclimatic conditions in India showed that neither organic manures nor mineral NPK fertilizers alone can produce high yields under intensive farming, where nutrient turnover in soil–plant system is large.^[27] Only less than 40% of the nutrients present in bulky organic manures are available to the first crop following their application, but may have notable residual effect. On the other hand, residues of high-quality organic inputs such

Table 2 Nutrient analysis of some common biofertilizers.

Manures	Nutrient content (percent)		
	N	P ₂ O ₅	K ₂ O
Fresh dung			
Cattle	0.3–0.4	0.1–0.2	0.1–0.3
Horse	0.3–0.4	0.3–0.4	0.3–0.4
Sheep	0.5–0.6	0.4–0.6	0.3–1.0

<i>Crotalaria juncea</i>	0.75	0.12	0.61

Source: From *Handbook of Agriculture*.^[26]

as green manures and legume tree pruning decompose quickly and may release 70–95% of their N within a season under tropical conditions,^[28] with a little impact on SOM content. The recovery of this released N may be 10–30% by the first crop and little, if any, for the second crop.^[29] The farmyard manure generally contains twice as much micronutrients as in *Sesbania* green manure on equal weight basis.^[30]

The crop residues contain appreciable amounts of plant nutrients and can contribute to soil quality. Prolonged removal or burning of the crop residues usually decreases soil nutrient reserves and SOM content.^[31] Increasing SOM content under tropical conditions often requires frequent and high doses of biosolids. Approximately 7 Mg/ha/yr dry matter of low-quality residues (roots and stems), or 10 Mg/ha/yr of high-quality residues (green manure leaves) may be required to maintain a 1% organic carbon in soils of the subhumid tropics.^[32]

CONCLUSION

There is a great scope for sustaining agricultural production through a judicious combination of mineral, organic, and microbial sources of plant nutrients. The dependence on chemical fertilizers can be reduced by supplementing the plant nutrients through the use of organic manures, green manures, crop residues, biofertilizers, and inclusion of legume crops in cropping sequences. This will lead to maintenance of soil productivity and improvement of soil physical conditions. There is a need for the development of simple, cost-effective, and easily adopted technologies for the production of organic manures. A judicious use of chemical fertilizers can reduce the risk of environment pollution because of reduction in use of fossil fuel for fertilizer production and low risks of contamination of natural waters. If the choice is to apply once within a rotation cycle, it may be applied to the most responsive crop in the sequence. Soil testing is an integral part of any INM program, and regular monitoring of soil health and diagnosis of nutrient availability are essential for minimizing risks of soil and environmental degradation.

International Soil Reference and Information Centre (ISRIC)

David Dent

Center for Sustainability Studies, Lund University, Lund, Sweden

Abstract

ISRIC–World Soil Information is an independent foundation, funded by the Netherlands Government with a mandate to increase knowledge of the land, its soils in particular, and to support the sustainable use of land resources; in short, to help people understand soils. Its aims are as follows: 1) to inform and educate, through the World Soil Museum; 2) to maintain and disseminate data for the scientific community through the International Council for Science World Data Centre for Soils which is the custodian of global and regional datasets, land resources maps, and reports; for many of these, ISRIC is the sole repository; 3) to conduct applied research on land resources and their management and to support the development of national and international policy. The institute has a tradition of welcoming guest researchers; and 4) the multilingual staff has expertise in taxonomy of soils, soil survey, land evaluation and land use planning, soil and water conservation, soil fertility, and data management and interpretation—globally and especially in tropical regions.

HISTORY

On the initiative of Professor F.A. van Baren, the International Society of Soil Science promoted the establishment of an international museum of soil standards to collect, analyze, and display the soils of the world, as depicted in the FAO–UNESCO Soil Map of the World. This was adopted by the General Council of UNESCO in 1964, and support was offered by the Government of the Netherlands.

The institute was founded in 1966 with working funds provided by the Ministry of Education, Culture, and Sciences of the Netherlands and administered by the International Institute for Aerospace Survey and Earth Sciences (ITC) in Enschede. At first, facilities were provided by the University of Utrecht; in 1977, the premises—which comprise the staff quarters, laboratory, workshop, teaching and conference facilities, and the world soils exhibition—in Wageningen were provided by the Netherlands Directorate General of International Cooperation.

In line with its evolving mandate and activities, the institute was renamed International Soil Reference and Information Centre (ISRIC) in 1974; it became a foundation with its own statutes and Board of Governors in 1995, registering the logo ISRIC–World Soil Information in 2004. The business arrangement with ITC was dissolved in 2002 and a cooperative agreement concluded with Wageningen University and Research Centre. It has a memorandum of understanding with FAO, including a joint program of work; close working relations are also maintained with UNESCO, United Nations Environment

Programme, and United Nations Convention to Combat Desertification.

WORLD SOIL MUSEUM

The World Soil Museum is the focus of an active educational program. Groups and individuals are welcome to the well documented, thematic exhibition of soil monoliths, representing the major soils of the world, their landscape relationships, and management. Several monoliths are on loan to museums and universities around the world (Figs. 1–4).

A new initiative, the ISRIC World of Soils, makes available through the Internet a wide range of educational resources: programs, pictures, data, and text. A UNESCO Chair in Land Resources is proposed as an international focus for soils education, to include ISRIC courses in taxonomy, soil survey, land evaluation, and land use planning, and database management and contributions from several partner institutions in the Netherlands and Switzerland.

Publications program includes new and updated standard technical works—in 2005 new editions of the FAO Guidelines for soil profile description and the Booker Soil Manual—and ISRIC Reports, which are available both online and in paper copy.

WORLD DATA CENTRE FOR SOILS

The World Data Centre for Soils serves the scientific community under the auspices of the International

Fig. 1 Collecting a soil monolith.

Council for Science (ICSU). Its role is to collect, scrutinize, analyze, and disseminate data and information worldwide, in particular to ICSU programs in global change, climate, and the environment. Data from ICSU programs are maintained and made freely available; a major project is under way to digitize the datasets and maps to make them available through the Internet or on DVD.

The principal holdings are in the following:

1. Monolith collection of more than 900 profiles, supported by some 5000 reference samples, fully analyzed by standard methods, representing the mapping units of the FAO–UNESCO Soil Map of the World^[1,2] and being extended to encompass the groups and lower-level units of the World Reference Base for Soil Resources.^[3]
2. ISRIC soil information system (ISIS) dataset, 800 profile descriptions with complete, validated, laboratory data, available online in SQL.
3. World Inventory of Soil Emission Potentials (WISE) dataset of 4000 profiles in the public domain compiled for global climatic change studies and backed up by a working database of more than 9500 profiles.

Fig. 2 Preparation of monolith in the workshop.

Fig. 3 Teaching in the World Soil Museum.

4. The Global Soil and Terrain (SOTER) datasets for South and Central America, Central and Eastern Europe, and Southern and Eastern Africa: spatial mapping units and geo-located point data at scales from 1.1 to 1.5 million, available online.
5. Soil and water conservation database of the World Overview of Conservation Approaches and Technologies (WOCAT).

For micromorphology, the following soil collections are available:

1. Systematic collection of 3500 large thin sections from the ISIS profiles.
2. STIBOKA-Jongerius collection of 10,000 large thin sections, mainly of Dutch soils.
3. Schmidt–Lorenz collection of more than 15,000 small thin sections of soils, mainly from Europe, Africa, Asia, and Australia.

There are excellent facilities for micromorphological examination and a common catalog is in preparation to make the collections publicly accessible.

Fig. 4 Display of monoliths.

APPLIED RESEARCH

The institute is well known for underpinning the Soil Map of the World, the Global Assessment of Human-induced Soil Degradation (GLASOD)^[4] produced for the Rio Conference in 1992, the World Reference Base for Soil Resources (since 1980), the SOTER database,^[5] and for interpretations of this information for land use planning and, further, in terms of sources and sinks of greenhouse

Fig. 7 Global SOTER coverage, December 2004.

gases (Figs. 5–7; Table 1). The institute is also a partner in the WOCAT (<http://www.wocat.net/>).

The trends in research over decades have been shifting away from data collection and toward putting the data to work and from solo soil science to work within multidisciplinary, international teams. An example is the study on the Pan-European Soil Erosion Assessment.^[6] Existing and future priorities include the following: a quantitative Global Assessment of Land Degradation and Improvement (GLADA), using 8 km definition satellite NDVI imagery to identify and delineate hotspots

for further characterization by 30 m definition Landsat imagery and subsequent field measurements by national teams; a policy initiative, Green Water Credits—akin to the Kyoto Protocol carbon credits mechanism—to build a global facility to pay rural land managers for water management services that are unrecognized and unrewarded, relieving poverty and enabling food and water security for everyone; and linking the SOTER and WOCAT databases with social rules to identify best-bet management practices and provide a learning network to support their application.

International Union of Soil Sciences

Stephen Nortcliff

Department of Soil Science, University of Reading, Reading, U.K.

Abstract

This entry briefly describes the history and development of the International Union of Soil Sciences (IUSS) from its foundation as the International Society of Soil Science (ISSS) in 1924 through its change to the IUSS in 1998 and then up to 2016. Brief details of the changing scientific structure of ISSS and IUSS together with the officers of the society/union are provided.

INTRODUCTION

In this entry, the history of the development of the International Society of Soil Science (ISSS) and its transformation into the International Union of Soil Sciences (IUSS) is briefly described. A brief historical review of soil science in the 19th century and early 20th century provides the context for the formation of the ISSS. Formed in 1924, ISSS arose from a series of international meetings and has probably been most widely known for organizing the World Congress of Soil Science on an approximately 4-year cycle. The initial organizational structure of ISSS was established in 1924 with six commissions and was not substantially altered until its demise in 1998, the major changes being the addition of two further commissions. The officers of ISSS initially consisted of the President (normally from the country which will next host the World Congress) and the Secretary-General. Subsequently, a Vice President and Deputy Secretary-General were appointed. As ISSS, the membership was based on individuals who subscribed separately. During the 1990s, ISSS sought membership of the International Council of Science (ICSU) and was accepted in 1993. The scientific members of ICSU are based on unions who have country members rather than individual members and this was recommended for ISSS. In 1998, ISSS ceased to exist and IUSS came into existence with its membership being based on National Soil Science Societies or similar bodies. The consequence of this change was a substantial increase in membership. The change to IUSS also saw a change in scientific structure with four “divisions” each divided into a number of “commissions.” The membership of ICSU has coincided with the development of stronger ties with other scientific unions.

THE HISTORICAL CONTEXT

In comparison to many of the sciences covered by other members of ICSU, soil science is a relatively young

science, and, for a number of years, many of those who might be considered as practicing soil scientists were not identified as such and were more likely to be found as members of other broad subject areas including chemistry, agriculture, and geology. These links with other branches of science continue and many practicing soil scientists will find themselves located in institutes and university departments which are not specifically described by the term “soil science.” If the subject matter addressed by soil scientist is similarly considered, it can be found that it is equally diverse with soil scientists employing tools and approaches derived from many sciences including physics, chemistry, biology, agriculture, earth sciences, and increasingly mathematical and related sciences.

Despite being a young science, the diversity of the scientific approaches employed within soil science has provided the stimulus for many scientists to focus their attention on this fascinating material. If one looks back to the early roots of the subject in the 19th century, a diversity of approaches can be found. In part, this early diversity might be ascribed to the context within which the soil scientists were working. In much of Western Europe, the focus for soil science was principally in the chemistry laboratory, where attempts were made to increase the agricultural productivity of land, with relatively little increase in the area farmed. There were a number of key players, such as J. B. Lawes, J. H. Gilbert, and J. von Liebig, who were particularly active during this time. In contrast, in Russia and the United States, there was considerably more land available for agricultural development and the principal approach to the study of soils was to address the spatial patterns and extent of soils, in part as guidance to land development. Again there were figures, such as V. V. Dokuchaev in Russia and C. F. Marbut in the United States, who made considerable contributions to our understanding of how soils developed and their patterns in the landscape.^[1] This latter approach has been described as “agrogeological.” In the early years, these two approaches were pursued separately with little or no direct contact

between them. The coming together of these two approaches resulted, among others, in the formation of the ISSS in 1924.

THE ESTABLISHMENT OF THE ISSS—STRUCTURE AND ORGANIZATION

The establishment of ISSS took place at the Fourth International Conference on Pedology which had taken place in Rome in 1924 with over 450 participants. A meeting held in 1922 under the title of the “Third International Conference on Pedology,” set the foundations for the establishment of the ISSS, establishing a broad structure including five commissions. In the next meeting (the Fourth International Conference on Pedology), held in Rome with over 450 participants, the proposal was put forward to establish the ISSS. The aims of the society were to develop more uniform methods of soil analysis, consider a uniform nomenclature for soil classification, produce agrogeological maps of Europe at scales of 1:0.5 million and 1:2.5 million, promote the establishment of soil science in countries without such developments, and promote soil science in the educational system. At this time, six commissions were established:

1. Soil physics.
2. Soil chemistry.
3. Soil biology.
4. Nomenclature and classification of soils.

5. Soil cartography.
6. Plant physiology in relation to pedology (subsequently changed to soil technology).

In 1956, at the Paris meeting, an additional commission (VII—“soil mineralogy”) was established, and at the Montpellier meeting in 1998, another commission (VIII—“soils and the environment”) was introduced.

Following the first meeting held in Rome, subsequent meetings of the society were designated as the World Congress of Soil Science and were to be held at locations around the world.

Also at this meeting, the first office bearers of the society were elected, with J. G. Lipman as the first President (setting the precedent that the President is from the host country of the next meeting of the World Congress of Soil Science) and D. J. Hissink from The Netherlands as the first Secretary-General (and Treasurer).

This organizational structure and the format of officers continued with minor modifications for the next 74 years, throughout the life of the ISSS. A list of the Presidents of ISSS and the location of the 16 World Congresses held by ISSS, which after an initial irregular pattern of meetings established a 4-year cycle (with the exception of the 6 years between the 9th and the 10th congresses) from the 6th congress in 1960 in Paris, is given in Table 1. The activity of the ISSS during the first 50 years is summarized in a special issue of the ISSS Bulletin published in 1974.^[2] The 4-year

Table 1 Presidents of ISSS and IUSS, location and dates of the World Congresses.

President	Country	Period of presidency	Location of congress	Year of congress
J. G. Lipman	United States	1924–1927	Washington, D.C.	1927

C. H. Edelman	The Netherlands	1950	Amsterdam	1950
R. Tavernier	Belgium	1950–1954	Leopoldville	1954
A. Oudin	France	1954–1956	Paris	1956
R. Bradfield	United States	1956–1960	Madison	1960
N. C. Cernescu	Romania	1960–1964	Bucharest	1964
E. G. Hallsworth	Australia	1964–1968	Adelaide	1968
V. A. Kovda	USSR	1968–1974	Moscow	1974
C. F. Bentley	Canada	1974–1978	Alberta	1978
J. S. Kanwar	India	1978–1982	New Delhi	1982
K. H. Hartge	Germany	1982–1986	Hamburg	1986
A. Tanaka	Japan	1986–1990	Kyoto	1990
A. A. Santelises	Mexico	1990–1994	Acapulco	1994
A. Ruellan	France	1994–1998	Montpellier	1998
S. Theerawong	Thailand	1998–2002	Bangkok	2002
D. Sparks	United States	2002–2006	Philadelphia	2006
R. S. Swift	Australia	2006–2010	Brisbane	2010
J. E. Yang	Korea	2010–2014	Jeju	2014

cycle of the World Congresses has continued with the change from ISSS to IUSS, with the 17th Congress being held in Bangkok, Thailand, in 2002; the 18th World Congress held in Philadelphia in 2006; the 19th World Congress held in Brisbane in 2010; and the 20th World Congress in Jeju, Korea, in 2014. During this time, the number of papers presented at the congresses has ranged from less than 200 in Oxford in 1935 to well over 2,000 in Bangkok in 2002, although there has been a shift from purely oral presentations to oral and poster presentations.

During the Council Meeting in Brisbane in 2010, a major change in the organization of the union was accepted. This was a move to decouple the presidency of the IUSS from the host of the World Congress of Soil Science, with a President elected from the whole membership of the union for a period of 2 years. Following the first election in 2012, R. Horn (Germany) was elected to serve as President from 2014 to December 2016. R. Lal (United States) was elected in 2014 to serve as Vice President from January 2015 to December 2016 and as President from January 2017 to December 2019. The Vice President (congress) represents the country hosting the World Congress of Soil Science on the Executive Committee and Council.

At the establishment of ISSS, it was recognized that to provide a degree of continuity to the society it was necessary to establish a bureau or secretariat which did not change with the presidency. Initially this comprised a Secretary-General/Treasurer, but subsequently the roles of secretary-general and treasurer were separated and the position of deputy Secretary-General was established. From 1924 to 2016, there have been just six holders of the position of Secretary-General (Table 2).

In 2014, the union changed its organizational structure with a move to a permanent secretariat based in Austria. This secretariat was partially funded by BIOS Science Austria which is a legal entity and a non-profit association comprising the main players in the life sciences in Vienna: The University of Natural Resources and Life Sciences, Vienna; the University of Veterinary Medicine; the Austrian Federal Ministry of Agriculture, Forestry, Environment and Water Management; the

Austrian Agency for Health and Food Safety; the Federal Research Center for Forests; the Umweltbundesamt (Environment Agency Austria); the Federal Office for Water Management; the Austrian Institute of Technology; and the Ecosocial Forum Europe. Dr. Sigbert Huber is the Secretary of IUSS in this new Structure and Dr. Moika Tulipan the Assistant Secretary.

Prior to 1998, membership of ISSS was on the basis of individual subscriptions, but with the shift to the structure of an International Union, the membership comprises national bodies, which depending upon the organizational structure in the individual countries may be the National Academies of Science or National Soil Science Societies. At the time of the Montpellier World Congress, the ISSS membership stood at a little over 7,000; under the new organizational structure where membership is through national bodies, the union represents well over 40,000 soil scientists globally.

IUSS—THE NEW SCIENTIFIC STRUCTURE

The change from ISSS to IUSS took place in 1998, and with this change, a new scientific structure was developed, with divisions as the highest level of organization. Commissions were identified as the organizational units within divisions, and “working groups” were established to address subject matter across divisional boundaries, or where topics were likely to be active over relatively short time periods.^[3] The four divisions are as follow:

1. Division 1—Soils in space and time.
2. Division 2—Soil properties and processes.
3. Division 3—Soil use and management.
4. Division 4—The role of soil in sustaining society and the environment.

Following additions in 2004 and 2010, the commissions within the divisions cover the following areas:

1. Division 1
 - C1.1 Soil morphology and micromorphology.
 - C1.2 Soil geography.
 - C1.3 Soil genesis.
 - C1.4 Soil classification.
 - C1.5 Pedometrics.
 - C1.6 Palaeopedology.
2. Division 2
 - C2.1 Soil physics.
 - C2.2 Soil chemistry.
 - C2.3 Soil biology.
 - C2.4 Soil mineralogy.
 - C2.5 Soil interfacial reactions.
3. Division 3
 - C3.1 Soil evaluation and land use planning.
 - C3.2 Soil and water conservation.
 - C3.3 Soil fertility and plant nutrition.

Table 2 Secretaries-General of ISSS/IUSS.

Secretary-General	Country	Period of office
D. J. Hissink	The Netherlands	1924–1950
F. A. van Baren	The Netherlands	1950–1974
R. Dudal	Belgium	1974–1978
W. G. Sombroek	The Netherlands	1978–1990
W. E. H. Blum	Austria	1990–2002
S. Nortcliff	United Kingdom	2002–2010
A. E. Hartemink	The Netherlands/United States	2010–2014

- C3.4 Soil engineering and technology.
- C3.5 Soil degradation control, remediation, and reclamation.
- C3.6 Salt affected soils.

4. Division 4

- C4.1 Soil and the environment.
- C4.2 Soil, food security, and human health.
- C4.3 Soil and land use change.
- C4.4 Soil education and public awareness.
- C4.5 History, philosophy, and sociology of soil science.

This structure and the 22 commissions serve to illustrate the changes and expansion of the subject matter of soil science from the original six commissions established in 1924. The subject matter of soil science has grown increasingly multidisciplinary, and many soil scientists have strong links with scientists in other scientific unions within the broad ICSU family including International Union of Geological Sciences (IUGS), International Union of Geodesy and Geophysics (IUGG) and International Geographical Union (IGU), addressing the broad aspects of geological, geophysical, and geographical sciences; International Union of Biological Sciences (IUBS) addresses biological sciences; International Union of Pure and Applied Chemistry (IUPAC) deals with pure and applied chemistry; International Union of Pure and Applied Physics (IUPAP) deals with pure and applied physics; International Union of Biochemistry and Molecular Biology (IUBMB) addresses biology and molecular biology; and International Union of Food Science and Technology (IUFOT) addresses many aspects of food science and food technology. Following the decision to become a scientific union, IUSS has been an active member of ICSU the International Council for Science.

CONCLUSIONS

IUSS is able to trace its heritage back to the early soil scientists who pioneered the analysis of soil in the laboratory and the understanding of the development and distribution of soils in the field. The move from the organizational structure of ISSS with its individual membership to that of IUSS as a member of ICSU, with membership being provided through national bodies, reflects the increasing multidisciplinary and interdisciplinary nature of the tasks facing soil scientists and the tools required to address these tasks. This new structure also enables the possibility of IUSS to provide support through national bodies for soil scientists who may have difficulties in fulfilling their scientific potential and actively participating in global soil science activities, for example, through the work of the divisions which have a small annual budget to support individual soil scientists or national bodies in pursuing activities related to the activities of the division. The change to an elected President with a supporting secretariat marks another shift in emphasis with the President taking on a broader role promoting Soil Science and Soil Scientists in Regional and International contexts.

Ion Exchange

Bryon W. Bache

Cambridge University, Cambridge, U.K.

Abstract

Many substances in the soil solution exist as ions, but in a typical agricultural or garden soil most of the anions (the negatively charged particles) exist as large and insoluble macroions. Thus, the solid matrix of soil has a negative charge, and to maintain electrical neutrality, positively charged cations are adsorbed onto the surface of the insoluble anions in a diffuse-ion swarm. This scenario facilitates *cation exchange*, whereby some of the adsorbed cations are exchanged for others.

INTRODUCTION

Nature and Origin of Cation Exchange

Many common substances exist as ions. The simplest example is common salt, sodium chloride. This innocuous and life-sustaining compound is made of two dangerous and highly reactive elements, sodium and chlorine. When these two elements react together, the sodium atom loses an electron, giving it a positive charge (Na^+), while the chlorine atom gains an electron, giving it a negative charge (Cl^-). The positively charged ions are *cations*; the negative ones are *anions*. In a salt solution, the sodium and chloride ions are not physically bonded together but are free to diffuse independently in solution, attracted to each other only by electrostatic charges. Hence, the original derivation of the term *ion* (from the Greek for “wanderer”) is applied generally to any charged particle.

CATION EXCHANGE

Cation exchange is best illustrated by conducting a simple experiment. Place a layer of dry soil about 5 mm deep into a funnel, supported by a filter paper. Leach the soil slowly with demineralized water to remove the bulk of any soluble salts present and discard this leachate. Then leach with 50 ml of water, but this time collect the leachate. (Although this will take some time, mixing the soil with coarse sand will speed up the process.) Next, leach the soil with 50 ml of a solution containing 2–3 g of ammonium chloride and again collect the leachate. Test both the water leachate and the ammonium chloride leachate for calcium by adding ammonium oxalate solution. The water leachate will be free of calcium but the ammonium chloride leachate will give a white precipitate of calcium oxalate, showing that ammonium ion (NH_4^+) has displaced calcium ion (Ca^{2+}) from the soil

surfaces into solution. Ammonium has *exchanged* for calcium. A diagrammatic representation of this exchange reaction is shown in Fig. 1.

Humus and clay are the two components of the soil matrix that contain the macroions responsible for cation exchange. Humus contains proton-donating functional groups on the surface of its molecules, which are undissociated at low pH but dissociate as the pH rises, to give a negatively charged surface. The most important of these is the carboxy group:

where R is the organic core. Clay consists of fine platy crystals of aluminosilicate minerals. The lattice of these minerals has a positive-charge deficiency caused by the isomorphous substitution of aluminum ion (Al^{3+}) for Si^{4+} or magnesium ion (Mg^{2+}) for Al^{3+} in the structure of the mineral, which gives the crystal a net negative charge.

EXCHANGEABLE CATIONS, CATION EXCHANGE CAPACITY, AND BASE CATION SATURATION

In most agricultural soils, the dominant exchangeable cation is Ca^{2+} , with lesser amounts of Mg^{2+} , sodium ion (Na^+), and potassium ion (K^+). These four are often termed *base cations*—i.e., the cations of the bases $\text{Ca}(\text{OH})_2$, $\text{Mg}(\text{OH})_2$, NaOH , and KOH . These should not to be confused with *basic cations*, of which MgOH^+ is an example. In contrast, the acid cation Al^{3+} is dominant in acid mineral soils and the hydrogen ion (H_3O^+) is dominant in acid organic soils.

The total amount of cations that may be exchanged is the *cation exchange capacity* (CEC) of the soil. The sum of the positive charge on these cations equals the negative charge on the soil surface. The convention for CEC units most consistent with the International System

Fig. 1 Diagrammatic representations of cation exchange: (A) the experiment described in the text and (B) the equilibrium between the surface and the solution.

of Units is “millimoles of charge per kilogram of dry soil,” i.e., $\text{mmol}(+)\text{kg}^{-1}$ for the cations and $\text{mmol}(-)\text{kg}^{-1}$ for the surface charge. A variety of experimental procedures has been developed to measure exchangeable cations and CEC.^[1] CEC values in mmolkg^{-1} may vary for clay minerals from 30 for kaolinite to 1200 for smectite and for soils from 50 for Oxisols to 2000 for Histosols.

The negative charge on humus is strongly pH dependent, so that apart from the nature and amounts of clay and humus, the most important variable affecting CEC is the pH of the soil (Fig. 2). Thus, when comparing different soils, CEC is conventionally measured at a standard pH, normally at the neutral point of pH 7.0 with an ammonium acetate buffer and NH_4^+ as the displacing cation, or at pH 8.2 with a triethanolamine buffer and barium ion (Ba^{2+}) as the displacing cation.

Conventions for measuring CEC at a standard pH are appropriate for near-neutral soils dominated by permanent-charge clays. However, it is clear from Fig. 2 that they result in a highly inflated CEC value for acid soils when compared with the natural field soil, and they are even less appropriate for variable-charge soils, which acquire pH-dependent positive and negative charges (see Fig. 2 and section Anion Exchange). In these circumstances, CEC measured with unbuffered salt solutions at field pH provides a better interpretative value. This *effective* CEC

Fig. 2 The effect of pH on CEC: (a) a humic topsoil; (b) a mineral subsoil; (c) a strongly weathered Oxisol, showing both CEC and AEC.

(ECEC) equals the sum of the exchangeable cations extracted from the soil, including both base and acid cations. Thus, the pH of measurement should always be stated for CEC data.

An important concept for acid soils is the *base cation saturation* (V). This is usually expressed as a percentage and is then given by

$$V = 100\Sigma\text{M}^+/\text{CEC} \quad (2)$$

where ΣM^+ is the sum of the exchangeable base cations, ΣM^+ and CEC are measured in the same units, and CEC is at pH 7.0.

CATION EXCHANGE EQUILIBRIA AND CATION SELECTIVITY

Cation exchange was first discovered by H.S. Thompson in 1850; a review of early related work was compiled by Kelley.^[2] Good accounts are given by Mott,^[3] Spósito,^[4] and McBride.^[5] Apart from the source of cation exchange (discussed earlier), most interest has focused on the relationship between the relative concentrations of different cations in solution and the amounts of surface-adsorbed cations, and how this varies for different exchange materials (e.g., silicate clay minerals, humus, and synthetic resins).

Fig. 1B shows the equilibrium between the adsorbed cations and those in the surrounding solution, all of which are free to diffuse within the constraints of electrical neutrality. This equilibrium is established rapidly, allowing the exchange reactions to occur when the solution concentrations are altered, as in the experiment described above, or when fertilizers, irrigation water, or environmental pollutants are added to soils. Theoretical approaches to quantify this equilibrium are important to predict cation behavior in soil processes. While rigorous thermodynamic treatments are complicated,^[6] simplified empirical treatments are often more satisfactory. This author has found the most useful to be the *corrected rational selectivity coefficient*,^[7] which incorporates the activities of the solution ions and the equivalent fraction of the adsorbed ions. *Activity* has been described as effective concentration and is usually a little lower than the actual concentration measured in mole/dm³. *Equivalent fraction* is the fraction of the total negative charge occupied by the adsorbed cation. In a simple homovalent exchange, such as potassium displacing sodium,

the selectivity coefficient **K** is given by as follows:

$$\mathbf{K} = \frac{X_{\text{K}} (\text{Na}^+)}{X_{\text{Na}} (\text{K}^+)} \quad (4)$$

where X is the equivalent fraction of ion on the exchanger and the parentheses indicate the activity of that ion in solution. This selectivity coefficient shows the preference of the exchanger for one ion over another. In this example, if **K** is less than 1, sodium would be preferred by the exchanger, but in practice **K** is greater than 1 and potassium is preferred.

For a heterovalent exchange reaction, such as calcium displacing sodium,

the selectivity coefficient is given by as follows:

$$\mathbf{K} = \frac{X_{\text{Ca}} (\text{Na}^+)^2}{[X_{\text{Na}}]^2 (\text{Ca}^{2+})} \quad (6)$$

using the same conventions as previously.

In general, cations with higher charge are more strongly adsorbed by exchangers (e.g., $\text{Al}^{3+} > \text{Ca}^{2+} > \text{Na}^+$) and for cations with similar charge, those with higher radius and lower hydration energy are preferred (e.g., $\text{Ba}^{2+} > \text{Ca}^{2+} > \text{Mg}^{2+}$). Structural considerations may also be involved. For example, the size of the potassium ion enables it to fit neatly into the holes on the surface of silicate clays, thereby increasing the preference of the surface for potassium.

PRACTICAL IMPORTANCE OF CATION EXCHANGE

This section outlines three of the many practical applications of cation exchange.

Plant Nutrition

Many plant nutrients exist as cations: the four base cations mentioned above, NH_4^+ , and the heavy metal cations such as iron ion (Fe^{2+}), copper ion (Cu^{2+}), zinc ion (Zn^{2+}), and manganese ion (Mn^{2+}).^[8] Plants take up their nutrients as simple ions from solution, but when the solution is depleted, *exchange desorption* allows the adsorbed cations to provide a reserve from which the solution may be replenished (Fig. 1). To maintain electrical neutrality, the desorption of one ion must be accompanied by adsorption of another, usually either Ca^{2+} (the most abundant cation) or the H_3O^+ , which plants excrete when they take up cation nutrients.

Soil Development and Acidification

In a humid climate, the course of soil development in a freely drained environment is always toward acidification.^[5,9] The H_3O^+ is strongly adsorbed and it exchanges for the base cations on the soil surfaces, which are then leached out, so that the soil gradually becomes more acid. The main sources of hydrogen ions are the dissolution of carbon dioxide, the release of organic acids when plant residues decompose, the deposition of atmospheric pollution, and the addition of fertilizer.

Amelioration of Saline and Alkali Soils

An excess of sodium salts and/or exchangeable sodium in these soils causes problems.^[5] Amelioration is effected by adding gypsum (CaSO_4) prior to leaching the soil with excess water. Calcium dissolves from the CaSO_4 and exchanges for sodium (as in the example of heterovalent exchange 5 above), which is then leached in the drainage water.

ANION EXCHANGE

Anion exchange^[3–5] can occur on positively charged surfaces in a manner similar to cation exchange on negative surfaces (e.g., as with synthetic resins based on quaternary ammonium groups).^[7] Although there are no soil minerals that possess permanent positive charges and humus does not acquire a positive charge, strongly weathered acid soils containing amorphous hydrated iron and aluminum oxides can acquire a pH-dependent positive charge:

This allows a small *anion exchange capacity* (AEC) to develop at a pH below 5, as shown in Fig. 2C, in addition to cation exchange on the negative surfaces of these variable-charge soils.^[3,10]

The main practical importance of anion exchange is that it allows the anions, namely Cl^- and nitrate ion (NO_3^-), to be resistant to leaching from the soil. This is particularly important for nitrate, which provides a reserve for plant nutrition. Phosphate has often been associated with anion exchange in the popular soil literature, but because its bonding to both neutral and positively charged sites is by hydroxyl ligand exchange rather than by diffuse-ion swarming, it is not genuinely “exchangeable” within the meaning of this entry.

Iron Oxides

Nikolla P. Qafoku

James Amonette

Pacific Northwest National Laboratory, Richland, Washington, U.S.A.

Abstract

Iron (Fe) oxides are common clay-sized oxide, oxyhydroxide, and hydroxide soil minerals. They are compounds of Fe, oxygen (O), and hydrogen (H) that have structures based on close-packed arrays of O. The octahedral and tetrahedral cavities within these arrays are filled with either Fe^{3+} or Fe^{2+} to form $\text{Fe}(\text{O}/\text{OH})_6$, FeO_6 , or FeO_4 structural units. All of the naturally occurring Fe oxide minerals usually undergo some degree of isomorphous substitution of other metal ions for Fe in their structures. Relatively simple techniques may be used to identify Fe oxides in the field based on their typical colors and magnetic properties. In the laboratory, a variety of instrumental techniques can be used to confirm phase identity and to quantify amount. Of these, X-ray diffraction, infrared spectroscopy, electron microscopy, thermal analysis, and Mössbauer spectroscopy are the most commonly used techniques. As oxides, the functional groups on their surfaces may have positive, negative, or no charge depending on pH and on the concentration and nature of other ions in the contact solution. A net positive surface charge usually is observed in soils because Fe oxides have a point of zero charge in the neutral or slightly basic pHs. The functional groups on the surface form complexes with cations and anions from the aqueous phase. Their sorption and electron-buffering properties significantly affect the geochemical cycles of almost all elements having agronomic or environmental significance.

INTRODUCTION

The iron (Fe) oxides are strongly pigmented clay-sized oxide, oxyhydroxide, and hydroxide minerals that occur in almost all soils and sediments. They are particularly abundant in highly weathered soils, where, in combination with aluminum (Al) and titanium (Ti) oxides, they may account for the great majority of the soil mass^[1] and the unique physical and chemical properties of these soils (Fig. 1). The sorptive properties of Fe oxides are largely determined by the interactions with the components of the soil solution such as protons and other dissolved ions. They also buffer the rich electron-transfer chemistry of Fe^{3+} and Fe^{2+} species. As a consequence of this sorptive and electrochemical reactivity, Fe oxides play a major role in the geochemical cycles of most elements having agronomic or environmental significance.

CLASSIFICATION AND OCCURRENCE

The Fe oxides are compounds of Fe, oxygen (O), and hydrogen (H) that have structures based on close-packed arrays of O. The octahedral and tetrahedral cavities within these arrays are filled with either Fe^{3+} or Fe^{2+} to form $\text{Fe}(\text{O}/\text{OH})_6$, FeO_6 , or FeO_4 structural units. The oxides are distinguished by the ways in which these structural units are arranged in space through corner, edge, or face

sharing. Of the 15 Fe oxides recognized, only 8 are commonly found in soils and sediments. Their selected properties are presented in Table 1.^[1–4]

Isomorphous Substitution

All of the naturally occurring Fe oxide minerals will undergo some degree of substitution of other metal ions for Fe in their structures. The isomorphous substitution of Al^{3+} for Fe^{3+} is most frequent and especially common in goethite. However, other trivalent cations with similar ionic radii to Fe^{3+} (e.g., Ti^{3+} , Mn^{3+} , Co^{3+} , Cr^{3+} , and V^{3+}) may replace Fe^{3+} in the Fe oxide structures. Cations with a higher (e.g., Ti^{4+}) or lower (e.g., Cu^{2+} and Zn^{2+}) valence may also substitute for Fe^{3+} but the extent of this substitution is not greater than 0.1 mol mol^{-1} .^[5] Substitution of Mg^{2+} for Fe^{2+} also occurs in green rusts and magnetites.

METHODS OF IDENTIFICATION

Bulk Analyses

The presence and total quantity of Fe in a soil (i.e., Fe_T) can be determined by a variety of spectroscopic techniques following hydrochloric acid or hydrofluoric acid digestion or non-destructively by energy-dispersive X-ray fluorescence. In some instances, determination of Fe valence is

Fig. 1 Fe-rich highly weathered soils from the Southeastern United States. (A) Tifton series (fine-loamy, siliceous, thermic Plinthic Kandiodults). (B) Faceville series (clayey, kaolinitic, thermic Typic Kandiodults).

important, and this can be performed by wet chemical techniques using colorimetry (1,10-phenanthroline) or oxidimetry (vanadate, argentous ion), or non-destructively using Mössbauer spectroscopy.^[6,7]

Relatively simple techniques may be used to identify Fe oxides in the field based on their typical colors and magnetic properties. In the laboratory, a variety of instrumental techniques can be used to confirm phase identity and to quantify amount. Of these, X-ray diffraction, infrared spectroscopy, electron microscopy, thermal analysis, and Mössbauer spectroscopy are the most commonly used techniques.

Selective Extractions

Operational measurements of Fe oxide content in soils are obtained using two selective extraction techniques that discriminate between crystalline and poorly ordered oxides on the basis of solubility under different conditions. The dithionite–citrate–bicarbonate (DCB) method nominally dissolves all pedogenic Fe oxides (crystalline and poorly ordered). This Fe fraction is termed Fe_{DCB}. The ammonium oxalate extraction (conducted in the dark) essentially

Table 1 Selected properties of iron oxides commonly found in soils and sediments.

Minerals		Chemical formula	Occurrence/formation	Color and morphology	Other properties
Oxides	Hematite	$\alpha\text{-Fe}_2\text{O}_3$	Humid tropical, subtropical, and Mediterranean soils (low organic matter and warm temperatures)	Blood-red, fine-grained, hexagonal plates	High stability and crystallinity
	Magnetite	Fe_3O_4	Inherited from parent materials but also produced by bacterial activity	Black, coarsely grained cubes	Contains both Fe^{2+} and Fe^{3+} , ferrimagnetic
	Maghemite	$\gamma\text{-Fe}_2\text{O}_3$	Highly weathered soils, especially Oxisols; formed by oxidation of magnetite or heating of goethite in the presence of organic matter	Brown, coarsely grained cubes	Has magnetite structure, ferromagnetic, minor Fe^{2+}
Oxyhydroxides	Goethite	$\alpha\text{-FeOOH}$	Most common Fe oxide in soils, especially under cool and wet conditions, rich in organic matter	Yellow, fine-grained stubby crystals with little acicularity	Highly stable, Al substitution common
	Lepidocrocite	$\gamma\text{-FeOOH}$	Seasonally anaerobic, non-calcareous soils in cool areas	Distinctive orange-colored laths	Similar to goethite, but little or no Al
	Schwertmannite	$\text{Fe}_8\text{O}_8(\text{OH})_6\text{SO}_4$	Acid-sulfate soils, and waters draining mine spoils and pyritic rocks	Dark yellow-orange clusters of fibrous crystals	Sulfate anion occupies tunnel structure
Hydroxides	Green rust	Variable $(\text{Fe}^{2+}_6\text{Fe}^{3+}_2)(\text{OH})_{16}\text{CO}_3 \cdot 2\text{H}_2\text{O}$	Transitory phase formed on rapid mixing of Fe^{2+} and Fe^{3+} salts under alkaline to neutral, slightly oxic conditions; may be produced by bacterial activity.	Distinctive blue-green, very fine-grained hexagonal plates	Contains Fe^{2+} and Fe^{3+} , reacts readily with oxidants; may contain Mg and anions besides CO_3^{2-}
	Ferrihydrite	$\sim\text{Fe}_5\text{HO}_8 \cdot 4\text{H}_2\text{O}$	Organic matter-rich soils subject to a rapid change from anoxic to oxic conditions; imprecise chemical formula	Brownish-orange spheres, 2–3 nm in diameter	Very poorly ordered, high surface area

Fig. 2 Fe oxides formation and transformation in soils.

Source: From Bigham, Fitzpatrick, et al.^[2]

dissolves only the Fe fraction that is present in the poorly ordered Fe oxides (Fe_{OX}). The difference between Fe_{DCB} and Fe_{OX} is an estimate of the crystalline Fe oxide fraction (Fe_{CRYS}) present in soils. Highly weathered soils typically have high Fe_{CRYS} values.

The Fe in silicate minerals (Fe_{SIL}), which is not dissolved appreciably by the DCB method, can be calculated as the difference of Fe_{T} and Fe_{DCB} . This Fe source may be mobilized during weathering and the ratio of Fe_{SIL} to Fe_{T} is a useful parameter in estimating the stage of soil weathering. Highly weathered soils (e.g., Oxisols and Ultisols) have small $\text{Fe}_{\text{SIL}}/\text{Fe}_{\text{T}}$ values.

FORMATION AND CHEMISTRY

Formation

The process of Fe oxide formation in soils (Fig. 2) starts with the oxidation of structural Fe^{2+} or aqueous Fe^{2+} that is released during the weathering of Fe^{2+} -bearing

primary minerals. In addition, Fe^{3+} may be released upon dissolution of Fe^{3+} oxides and Fe^{3+} -bearing minerals. Ferromagnesian silicates (e.g., olivines, pyroxenes, amphiboles, and micas) and Fe-Ti oxides are the primary Fe-bearing minerals and serve as a weatherable source of Fe in soils. Usually, minerals that contain Fe^{2+} are less stable because structural Fe^{2+} may oxidize to Fe^{3+} , creating a charge imbalance that weakens the structure of the mineral and promotes dissolution.^[2] Depending on the rate and extent of oxidation, the pH, and the presence of various anions in the solution, ferrihydrite, goethite, schwertmannite, or green rust will directly precipitate from the solution. Rapid oxidation, which results in a higher Fe^{3+} activity in the soil solution, promotes the formation of ferrihydrite. Goethite forms when the soil is rich in organic matter, inorganic colloids, or biological exudates that may sorb or complex Fe^{3+} , thus decreasing the activity of the free aqueous ions. Schwertmannite forms at low pH and high SO_4^{2-} typical of acid mine drainage. Green rust forms when oxidation is very slow and incomplete and when pH is neutral or higher. Continued slow oxidation of green rust

under high CO_3^{2-} conditions and dissolution of ferrihydrite and schwertmannite eventually lead to the formation of goethite. Rapid oxidation of green rust under slightly acidic, low- CO_3^{2-} conditions forms lepidocrocite. Slow oxidation of green rust under slightly alkaline, low- CO_3^{2-} conditions forms magnetite. Hematite forms by a solid-state transformation of ferrihydrite (predominantly) or magnetite. Maghemite forms by the oxidation of lithogenic magnetite or by the transformation of other Fe oxides by heating above 300°C in the presence of organic compounds. Hematite, goethite, maghemite, and lepidocrocite are the most stable Fe oxides, although only hematite and goethite are thermodynamically stable under ambient conditions.^[8] The abundance of goethite in soils stems from the many pathways by which it can form, coupled with its high thermodynamic stability.^[2]

Chemistry

Fe oxides are one of the end products of the weathering process in soils. They form clay-sized domains as small as a few nanometers across (e.g., ferrihydrite) and have specific surfaces ranging as high as several hundreds of $\text{m}^2 \text{g}^{-1}$. Even crystalline Fe oxides (e.g., goethite) may have specific surfaces of several tens of $\text{m}^2 \text{g}^{-1}$. Aggregation and cementation of clay-sized domains lead to larger particles, and even massive deposits, in some soils. As oxides, the functional groups on their surfaces may have positive, negative, or no charge depending on the pH and on the concentration and nature of other ions in the contact solution. A net positive surface charge is usually observed in soils because Fe oxides have a point of zero charge in the neutral or slightly basic pHs. The functional groups on the surface form complexes with cations and anions from the aqueous phase. Oxyanions (e.g., phosphate) are particularly strongly bound as they form innersphere complexes in which an anion oxygen becomes part of the oxide surface structure. The positive charge on the oxide surfaces may also be electrostatically attracted to the permanent negative charge on layered aluminosilicate clay minerals. Formation of electrostatic bonds between oxide and phyllosilicate minerals promotes the formation of soil aggregates and stabilizes them, especially in highly weathered variable-charge soils (Fig. 3).

Fe oxides also buffer the oxidation–reduction activity of soils. The standard reduction potential for the aqueous $\text{Fe}^{3+}/\text{Fe}^{2+}$ couple (+ 0.77 V) is situated in the middle of the limits for aqueous chemistry (i.e., –1.1 to +1.8 V), and Fe^{3+} in the poorly ordered oxides serves as a terminal electron acceptor for microorganisms once oxygen and nitrate are consumed. Under these anoxic conditions, large quantities of soluble Fe^{2+} may be generated and become mobile. The crystalline Fe oxides are less susceptible to reductive dissolution and can adsorb and react with some of these mobile Fe^{2+} cations on their surfaces,^[9] where they become much more effective reductants for environmental

Fig. 3 Interactions among positively charged Fe oxides and negatively charged phyllosilicates in Fe-rich soils.

contaminants.^[10–12] The concentrations of aqueous Fe^{2+} in soils may be as high as $10^{-4} \text{ mol L}^{-1}$, whereas that of Fe^{3+} is typically much lower (about $10^{-12} \text{ mol L}^{-1}$) because of the low solubility of Fe^{3+} oxides at neutral and alkaline pH. Fe oxides surface chemistry and interactions with soil organic matter, plants and microbes are discussed in the following publications.^[13–16]

NANO Fe MINERALS

Soil scientists have always paid special attention to the smallest fraction in soils, or the so-called “fine-grained,” “submicron,” “ultrafine,” or “nano” fraction, because of its large surface area, percentage of surface atoms with unbalanced charge, and number of surface functional groups per unit of mass.^[17] Fe oxyhydroxides are an integral part of the soil nano fraction. Ferrihydrite, for example, exists only as a nanoparticle and larger equivalents of this soil mineral do not even exist.^[18] Despite the ubiquity of ferrihydrite in natural sediments and the fact that ferrihydrite has been subject to intensive research, the nanocrystallinity of this Fe oxyhydroxide has hampered accurate structure determination by traditional methods that rely on long-range order, and its exact structure and composition is still a matter of debate.^[19] Nano Fe oxyhydroxides in soils manifest unique size-dependent properties including point of zero charge,^[20] adsorption edge,^[21] kinetics of reductive dissolution,^[22] solubility,^[4] and electron-transfer reactivity.^[23]

FURTHER READING

For more detailed treatment of the classification, structure and chemistry of the iron oxides in soils, several excellent reviews,^[1–4,9] and two books^[5,6] are recommended. For a discussion of methods used to characterize Fe oxide and other soil minerals see the work of Amonette & Zelazny.^[7] Environmental chemistry of Fe is discussed in the following references.^[9–13] A broader discussion of the role of nanoparticles in soils and related geosystems can be found in the work of Qafoku.^[17]

CONCLUSION

Fe oxides are one of the most important mineralogical components in soils. They primarily form by the oxidation of Fe²⁺ that is dissolved during the weathering processes. Because they occur as clay-sized particles having high specific surfaces, they substantially contribute to the physical and chemical properties of the soil. Their sorption and electron-buffering properties significantly affect the geochemical cycles of almost all elements having agronomic or environmental significance.

Irrigation

Jack Keller

Keller Bliesner Eng. LLC, Logan, Utah, U.S.A.

Abstract

The basic idea behind irrigation is to supply water and store water in soils for later use by plants where or when insufficient water for the desired level of plant growth is supplied by natural precipitation. There are three basic methods used for supplying irrigation water to the surface of soils and two for applying water beneath the soil surface.

IRRIGATION METHODS

The three application methods for applying water to the surface of soils are: 1) surface irrigation, where the soil surface is used to convey the irrigation water where it will be stored in the soil; 2) sprinkle irrigation, where the water is sprinkled on the soil surface where it is to be stored; and 3) drip irrigation, where the water is directly applied by dripping or being sprayed from small holes in the pipe network where it is to be stored in the soil. The two methods for applying irrigation water beneath the soil surface are: 1) subsurface drip irrigation, where the network of pipe and outlets is buried beneath the soil surface and 2) subirrigation, where the water table is controlled and the water reaches the plant root system through capillary action.

These methods of irrigation and irrigation efficiency issues are discussed in detail in other sections of this encyclopedia.

WATER STORAGE CAPACITY OF SOILS

Understanding basic soil–water–plant relationship is central to the ability to design and manage irrigation systems. The tables related to soil water presented in this section provide useful guidelines for estimating irrigation requirements and for preliminary irrigation design purposes. However, more site-specific information should be used for designing and managing irrigation systems and evaluating irrigation system performance.

Soil Water-Holding Capacity

Soils of various textures have varying abilities to retain water. Except for required periodic leaching, any irrigation beyond the field capacity of the soil is an economic loss. [Table 1](#) gives typical ranges of available water-holding capacities (field capacity minus permanent wilting point)

of soils of different textures. [Table 1](#) should only be used as a guide for preliminary system designs and management purposes. Final designs and management decisions should be based on actual field data.

Root Depth

The total amount of soil water available for plant use in any soil is the sum of the available water-holding capacities of all soil horizons occupied by plant roots. Typical plant feeder root and total root depth are given in many references; however, the actual depths of rooting of the various crops are affected by soil conditions. Therefore, the root depth for any set of crop and site should be checked. Where local data are not available and there are no expected root restrictions, [Table 2](#) can be used as a guide to estimating the effective root depths. The values given are taken by Keller and Bliesner and are based on the author's estimate of averages selected from a large number of references. They represent the depth at which crops will obtain the major portion of the water they need when grown in a deep, well-drained soil that is adequately irrigated.

CONSUMPTIVE USE AND DESIGN

Deciding how much water an irrigation system should be able to deliver to a crop over a given period is ultimately a question of selecting a capacity that will maximize profits to the farmer. To begin to address this question of system capacity, it is necessary to know how much water a crop will use over the entire growing season and during the part of the season when water use is at its peak. The rate of water use during this peak period provides the basis for determining the rate at which irrigation water should be delivered to the field. Examples of typical seasonal and peak daily crop water requirements are given in [Table 3](#).

Table 1 Range in available water-holding capacity of soils of different texture.

Soil texture	Water-holding capacity	
	Range (mm/range)	Average (mm/range)
Very coarse texture—very coarse sands	33–62	42
Coarse texture—coarse sands, fine sands, and loamy soils	62–104	83
Moderately coarse texture—sandy loams	104–145	25
Medium texture—very fine sandy loams, loams, and silt loams	125–192	167
Moderately fine texture—clay loams, silty clay loams, and sandy clay loams	145–208	183
Fine texture—sandy clays, silty clays, and clays	133–208	192
Peats and mucks	167–250	208

SOIL MOISTURE MANAGEMENT

A general rule of thumb for many field crops in arid and semiarid regions is to maintain the soil moisture deficit (SMD) within the root zone above 50% of the total available water-holding capacity. This is a management-allowed deficit (MAD = 50%) because it is also desirable to bring the moisture level back to field capacity with each irrigation. (In humid regions, it is necessary to allow for rains during the irrigation period. However, the 50% limitation on soil moisture depletion should be followed as a general guide for field crops.)

Soil management, water management, and economic considerations determine the amount of water used in irrigating and the rate of water application. The standard approach has been to determine the amount of water needed to fill the entire root zone to field capacity and then to apply a sufficiently larger amount to account for evaporation, leaching, and efficiency of application. The traditional approach to the frequency of application has been to take the depth of water in the root zone reservoir that can be extracted assuming MAD = 50% and, using the daily consumptive use rate of the crop, to determine how long this supply will last. Such an approach is useful only as a guide to irrigation requirements, as many factors affect the volume and timing of applications for optimal design and operation of a system.

Table 4 is presented as a guide for selecting the appropriate MAD or for near optimum production of various crops. As indicated in Table 4 for crops with a high market value, it is often profitable to irrigate well before

^aApproximately 80% of the feeder roots are in the top 60% of the soil profile. Soil and plant environmental factors often offset normal root development; therefore, soil density, pore shapes and sizes, soil–water status, aeration, nutrition, texture and structure modification, soluble salts, and plant root damage by organisms should all be taken into account.

Source: Adapted from Keller & Bliesner.^[2]

half of the soil moisture in the root zone has been depleted, i.e., SMD = 50%.

Irrigation Depth

The maximum net depth of water to be applied per irrigation, d_x , is the same as the maximum allowable depletion of soil water between irrigations. Assuming no additional water is necessary for leaching purposes, it is computed by as follows:

$$d_x = \frac{MAD}{100} W_a Z \quad (1)$$

where d_x is maximum net depth of water to be applied and stored in the root zone per irrigation event [mm (in.)]; MAD is management-allowed deficit, which can be estimated

from Table 4 (%); W_a is available water-holding capacity of the soil, which can be estimated from Table 1 [mm/m (in./ft)]; and Z is effective root depth, which can be taken from Table 2 [mm (ft)].

Irrigation Interval

The appropriate irrigation interval, which is the time that should elapse between the beginning of two successive irrigation events, is determined by as follows:

$$f' = \frac{d_n}{U_d} \quad (2)$$

where f' is irrigation interval or frequency (days); d_n is net depth of water applied and stored in the soil per irrigation event, to meet consumptive use requirements [mm (in.)]; U_d is conventionally computed average daily crop water requirement, or use rate, during the peak-use month, which can be estimated from Table 3 [mm/day (in./day)].

The value selected for d_n will depend upon system design and environmental factors and should be equal to or less than d_x . When d_n is replaced by d_x in Eq. 2, f' becomes the maximum irrigation interval, f_x .

IRRIGATION SYSTEM DESIGN, MANAGEMENT, AND SCHEDULING

General Design Concepts

Design of all irrigation systems is process of synthesis, where properties, such as a soil's intake rate and crop water requirements; items, such as canals, pipes, and pumps; and processes, such as trenching, coaxing water down furrows, or moving pipe, must be integrated to form a good irrigation system. The irrigation designer's art is to know the kinds of hardware and management techniques appropriate for a given cropping system and site and to have a clear mental image of what the system can accomplish and how the completed system will appear. Careful site analysis is essential as it provides data that lead to an understanding of the physical, economic, and social resources that determine what can and ought to be accomplished by a proposed irrigation system.

Generally, irrigation systems are designed to meet average peak water use requirements. Sometimes, to reduce costs or to stretch limited water supplies, systems are designed to optimize production per unit of water applied. In such cases, systems can be designed to apply only about 80% of peak water requirements and still obtain up to 95% of optimum yields. For deep-rooted crops in fine-textured soils, an appreciable amount of water can be stored prior to the critical peak-use periods. By drawing on this stored water, peak system delivery

requirements can be reduced without reducing yield potential providing the quality of the irrigation water is high.

Salinity Control

All irrigation water contains some dissolved salts that are pushed downward by rainfall and application of irrigation water. By applying more water than the plants consume, most of the salts can be pushed or leached below the root zone. The first step in computing the additional water

required for leaching is to determine the leaching requirement by:

$$LR = \frac{EC_w}{5EC_e - EC_w} \quad (3)$$

where LR is leaching requirement ratio for sprinkle or surface irrigation; EC_w is electrical conductivity of the irrigation water [dS/m (mmhos/cm)]; EC_e is estimated electrical conductivity of the average saturation extract of the soil root zone profile for an appropriate yield reduction [dS/m (mmhos/cm)].

Unless more specific information on specific crop cultivars is available, the EC_e values presented in Table 5, which are taken by Ayers and Westcott,^[3] can be used in Eq. 3. These are values that will give an approximate 10% yield reduction, as presented by Ayers and Westcott.^[3] (For conversion purposes, 1.0 ppm = 640 × EC in dS/cm.)

Under full irrigation, where $LR < 0.1$, the annual deep percolation losses—even in most of the least watered areas—will normally be sufficient to provide the necessary leaching. However, under deficit irrigation or when $LR < 0.1$, water in addition to the consumptive use should be applied or available at some time during the year to satisfy leaching requirements. The ratio of the total depth

of irrigation water required with and without leaching is equal to $1/(1 - LR)$.

Drainage

Drainage of the excess water from the soil profile and conveying it to a sump for reuse or disposal is as important as irrigation. In fact natural or man-made subsurface drainage is essential for sustaining irrigated agricultural production. Without it leaching will not be possible, causing salts to accumulate until they become toxic to plant growth, and the water table will rise and literally drown the plants. Furthermore, the productive capability of the land itself may be severely damaged and require major reclamation to become productive again. Details regarding drainage needs are presented elsewhere in this encyclopedia.

Application Depth and Frequency

For periodic-move, and low-frequency, continuous-move systems, such as traveling sprinklers, it is desirable to irrigate as infrequently as practical to reduce labor costs and

Eq. 1 will apply. For drip solid-set and center-pivot sprinkle systems, labor costs are not a major consideration and the irrigation frequency can be selected to provide the optimal environment for plant growth, water conservation, and economic production within the physical limitations of the system.

Systems are usually designed so that their discharge, depths of application, and irrigation frequency meet crop water requirements during the peak consumptive use period. Therefore, systems must be managed to avoid wasting water, labor, and energy, and leaching nutrients from the soil during periods of the crops' growth cycle when water requirements are less, when the crops' roots may not have penetrated to their full depth, and during rainy periods. For optimum efficiency, irrigation applications should be scientifically scheduled from water

budgets based on crop evapotranspiration estimates or soil moisture observations.

Irrigation: Efficiency

Terry A. Howell

Conservation and Production Research Laboratory, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Bushland, Texas, U.S.A.

Abstract

Irrigation efficiency is an important engineering term that involves understanding soil and agronomic sciences to achieve the greatest benefit from irrigation. The enhanced understanding of irrigation efficiency can improve the beneficial use of limited and declining water resources needed to enhance crop and food production from irrigated lands.

INTRODUCTION

Irrigation efficiency is a critical measure of irrigation performance in terms of the water required to irrigate a field, farm, basin, irrigation district, or an entire watershed. The value of irrigation efficiency and its definition are important to the societal views of irrigated agriculture and its benefit in supplying the high-quality, abundant food supply required to meet our growing world's population. "Irrigation efficiency" is a basic engineering term used in irrigation science to characterize irrigation performance, to evaluate irrigation water use, and to promote better or improved use of water resources, particularly those used in agriculture and turf/landscape management.^[1–4] Irrigation efficiency is defined in terms of: 1) the irrigation system performance; 2) the uniformity of the water application; and 3) the response of the crop to irrigation. Each of these irrigation efficiency measures is interrelated and will vary with scale and time. Fig. 1 illustrates several of the water transport components involved in defining various irrigation performance measures. The spatial scale can vary from a single irrigation application device (a siphon tube, a gated pipe gate, a sprinkler, and a microirrigation emitter) to an irrigation set (basin plot, a furrow set, a single sprinkler lateral, or a microirrigation lateral) to broader land scales (field, farm, an irrigation canal lateral, a whole irrigation district, a basin or watershed, a river system, or an aquifer). The timescale can vary from a single application (or irrigation set), a part of the crop season (preplanting, emergence to bloom or pollination, or reproduction to maturity), the irrigation season, to a crop season, or a year, partial year (premonsoon season, summer, etc.), or a water year (typically from the beginning of spring snow melt through the end of irrigation diversion, or a rainy or monsoon season), or a period of years (a drought or a "wet" cycle). Irrigation efficiency affects the economics of irrigation, the amount of water needed to irrigate a specific land area, the spatial uniformity of the crop and its yield, the amount of water that might percolate beneath the crop root

zone, the amount of water that can return to surface sources for downstream uses or to groundwater aquifers that might supply other water uses, and the amount of water lost to unrecoverable sources (salt sink, saline aquifer, ocean, or unsaturated vadose zone).

The volumes of the water for the various irrigation components are typically given in units of depth (volume per unit area) or simply the volume for the area being evaluated. Irrigation water application volume is difficult to measure, so it is usually computed as the product of water flow rate and time. This places emphasis on accurately measuring the flow rate. It remains difficult to accurately measure water percolation volumes, groundwater flow volumes, and water uptake from shallow ground water.

IRRIGATION SYSTEM PERFORMANCE EFFICIENCY

Irrigation water can be diverted from a storage reservoir and transported to the field or farm through a system of canals or pipelines; it can be pumped from a reservoir on the farm and transported through a system of farm canals or pipelines; or it might be pumped from a single well or a series of wells through farm canals or pipelines. Irrigation districts often include small to moderate size reservoirs to regulate flow and to provide short-term storage to manage the diverted water with the on-farm demand. Some on-farm systems include reservoirs for storage or regulation of flows from multiple wells.

Water Conveyance Efficiency

The conveyance efficiency is typically defined as the ratio between the water that reaches a farm or field and that diverted from the irrigation water source.^[1,3,4] It is defined as

$$E_c = 100 \frac{V_f}{V_t} \quad (1)$$

Fig. 1 Illustration of the various water transport components needed to characterize irrigation efficiency.

where E_c is the conveyance efficiency (%), V_f is the volume of water that reaches the farm or field (m^3), and V_t is the volume of water diverted (m^3) from the source. E_c also applies to segments of canals or pipelines, where the water losses include canal seepage or leaks in pipelines. The global E_c can be computed as the product of the individual component efficiencies, E_{ci} , where i represents the segment number. Conveyance losses include any canal spills (operational or accidental) and reservoir seepage and evaporation that might result from management as well as losses resulting from the physical configuration or condition of the irrigation system. Typically, conveyance losses are much lower for closed conduits or pipelines^[4] compared with unlined or lined canals. Even the conveyance efficiency of lined canals may decline over time due to material deterioration or poor maintenance.

Application Efficiency

Application efficiency relates to the actual storage of water in the root zone to meet the crop water needs in relation to the water applied to the field. It might be defined for individual irrigations or parts of irrigations (irrigation sets). Application efficiency includes any application losses to evaporation or seepage from surface water channels or furrows, any leaks from sprinkler or drip pipelines, percolation beneath the root zone, drift from sprinklers, evaporation of droplets in the air, or runoff from the field. Application efficiency is defined as

$$E_a = 100 \frac{V_s}{V_f} \quad (2)$$

where E_a is the application efficiency (%), V_s is the irrigation needed by the crop (m^3), and V_f is the water delivered to the field or farm (m^3). The root zone may not need to be fully refilled, particularly if some root zone water-holding capacity is needed to store possible or likely rainfall. Often, V_s is characterized as the volume of water stored in the root zone from the irrigation application. Some irrigations may be applied for reasons other than meeting the crop water requirement (germination, frost control, crop cooling, chemigation, fertigation, or weed germination). The crop need is often based on the “beneficial water needs.”^[5] In some surface irrigation systems, the runoff water that is necessary to achieve good uniformity across the field can be recovered in a “tailwater pit” and recirculated with the current irrigation or used for later irrigations, and V_f should be adjusted to account for the “net” recovered tailwater. Efficiency values are typically site specific. Table 1 provides a range of typical farm and field irrigation application efficiencies^[6–8] and potential or attainable efficiencies for different irrigation methods that assume irrigations are applied to meet the crop need.

Storage Efficiency

Since the crop root zone may not need to be refilled with each irrigation, the storage efficiency has been defined.^[4] The storage efficiency is given as

$$E_s = 100 \frac{V_s}{V_{rz}} \quad (3)$$

where E_s is the storage efficiency (%) and V_{rz} is the root zone storage capacity (m^3). The root zone depth and the water-holding capacity of the root zone determine V_{rz} . The storage efficiency has little utility for sprinkler or microirrigation because these irrigation methods seldom refill the root zone, while it is more often applied to surface irrigation methods.^[4]

Seasonal Irrigation Efficiency

The seasonal irrigation efficiency is defined as

$$E_i = 100 \frac{V_b}{V_f} \quad (4)$$

where E_i is the seasonal irrigation efficiency (%) and V_b is the water volume beneficially used by the crop (m^3). V_b is somewhat subjective,^[4,5] but it basically includes the required crop evapotranspiration (ET_c) plus any required leaching water (V_l) for salinity management of the crop root zone.

Leaching requirement (or the leaching fraction)

The leaching requirement,^[9] also called the leaching fraction, is defined as

Table 1 Example of farm and field irrigation application efficiency and attainable efficiencies.

Source: From Howell,^[6] Merriam & Keller,^[7] and Hart.^[10]

$$L_t = \frac{V_d}{V_f} = \frac{EC_i}{EC_d} \quad (5)$$

where L_r is the leaching requirement, V_d is the volume of drainage water (m^3), V_f is the volume of irrigation (m^3) applied to the farm or field, EC_i is the electrical conductivity of the irrigation water ($dS\ m^{-1}$), and EC_d is the electrical conductivity of the drainage water ($dS\ m^{-1}$). The L_r is related to the irrigation application efficiency, particularly when drainage is the primary irrigation loss component. The L_r would be required “beneficial” irrigation use

$$V_l \equiv L_T V_i$$

so only V_d greater than the minimum required leaching should reduce irrigation efficiency. Then, the irrigation efficiency can be determined by combining Eqs. 4 and 5.

$$E_i = 100 \left(\frac{V_b}{V_f} + L_T \right) \quad (6)$$

Burt et al.^[5] defined the “beneficial” water use to include possible off-site needs to benefit society (riparian needs or wildlife or fishery needs). They also indicated that V_f should not include the change in the field or farm storage of water, principally soil water but it could include field (tailwater pits) or farm water storage (a reservoir) that was not used within the time frame that was used to define E_i .

IRRIGATION UNIFORMITY

The fraction of water used efficiently and beneficially is important for improved irrigation practice. The uniformity of the applied water significantly affects irrigation efficiency. This uniformity is a statistical property of the applied water’s distribution. This distribution depends on many factors that are related to the method of irrigation, soil topography, soil hydraulic or infiltration characteristics, and hydraulic characteristics (pressure, flow rate, etc.) of the irrigation system. Irrigation application distributions are usually based on depths of water (volume per unit area);

however, for microirrigation systems, they are usually based on emitter flow volumes because the entire land area is not typically wetted.

Christiansen's Uniformity Coefficient

Christiansen^[11] proposed a coefficient intended mainly for sprinkler systems based on the catch volumes given as

$$C_U = 100 \left[\frac{1 - (\sum |X - \bar{x}|)}{\sum X} \right] \quad (7)$$

where C_U is the Christiansen's uniformity coefficient (%), X is the depth (or volume) of water in each of the equally spaced catch containers (mm or ml), and $\bar{x}$ is the mean depth (volume) of the catch (mm or ml). For C_U values >70%, Hart^[10] and Keller and Bliesner^[8] presented

$$C_U = 100 \left[1 - \left(\frac{\sigma}{\bar{x}} \right) \left(\frac{2}{\pi} \right)^{0.5} \right] \quad (8)$$

where σ is the standard deviation of the catch depth (mm) or volume (ml). Eq. 8 approximates the normal distribution for the catch amounts.

The C_U should be weighted by the area represented by the container^[12] when the sprinkler catch containers intentionally represent unequal land areas, as is the case for catch containers beneath a center pivot. Heermann and Hein^[12] revised the C_U formula (Eq. 8) to reflect the weighted area, particularly intended for a center pivot sprinkler, as follows:

$$C_{U(H\&H)} = 100 \left\{ 1 - \left[\frac{\left(\sum S_i |V_i - \left(\frac{\sum V_i S_i}{\sum S_i} \right)| \right)}{\sum (V_i S_i)} \right] \right\} \quad (9)$$

where S_i is the distance (m) from the pivot to the i th equally spaced catch container and V_i is the volume of the catch in the i th container (mm or ml).

Low-Quarter Distribution Uniformity

The distribution uniformity represents the spatial evenness of the applied water across a field or a farm as well as within a field or farm. The general form of the distribution uniformity can be given as

$$D_{Up} = 100 \left(\frac{\bar{V}_p}{\bar{V}_f} \right) \quad (10)$$

where D_{Up} is the distribution uniformity (%) for the lowest p fraction of the field or farm (lowest one-half $p = 1/2$, lowest one-quarter $p = 1/4$), $\bar{V}_p$ is the mean application volume (m^3), and $\bar{V}_f$ is the mean application volume (m^3) for the whole field or farm. When $p = 1/2$ and $C_U > 70\%$, then the D_U and C_U are essentially equal.^[13] The

USDA-NRCS (formerly, the Soil Conservation Service) has widely used D_{U1q} ($p = 1/4$) for surface irrigation to access the uniformity applied to a field, i.e., by the irrigation volume (amount) received by the lowest one-quarter of the field from applications for the whole field. Typically, D_{Up} is based on the post-irrigation measurement^[5] of water volume that infiltrates the soil because it can more easily be measured and better represents the water available to the crop. However, the post-irrigation infiltrated water ignores any water intercepted by the crop and evaporated and any soil water evaporation that occurs before the measurement. Any water that percolates beneath the root zone or the sampling depth will also be ignored.

The D_U and C_U coefficients are mathematically interrelated through the statistical variation (coefficient of variation, $\sigma/\bar{x}$, C_v) and the type of distribution. Warrick^[13] presented relationships between D_U and C_U for normal, log-normal, uniform, specialized power, and beta and gamma distributions of applied irrigations.

Emission Uniformity

For microirrigation systems, both the C_U and D_U concepts are impractical because the entire soil surface is not wetted. Keller and Karmeli^[14] developed an equation for microirrigation design as follows

$$E_U = 100 \left[1 - 1.27(C_{vm})n^{-1/2} \right] \left(\frac{q_m}{\bar{q}} \right) \quad (11)$$

where E_U is the design emission uniformity (%), C_{vm} is the manufacturer's coefficient of variability in emission device flow rate (1 hr^{-1}), n is the number of emitters per plant, q_m is the minimum emission device flow rate (1 hr^{-1}) at the minimum system pressure, and $\bar{q}$ is the mean emission device flow rate (1 hr^{-1}). This equation is based on the D_{U1q} concept^[4] and includes the influence of multiple emitters per plant that each may have a flow rate from a population of random flow rates based on the emission device manufacturing variation. Nakayama et al.^[15] developed a design coefficient based more closely on the C_U concept for emission device flow rates from a normal distribution given as

$$C_{Ud} = 100(1 - 0.798(C_{vm})n^{-1/2}) \quad (12)$$

where C_{Ud} is the coefficient of design uniformity (%) and the numerical value, 0.798, is

$$\left(\frac{2}{\pi} \right)^{0.5}$$

from Eq. 8.

Many additional factors affect microirrigation uniformity including hydraulic factors, topographic factors, and emitter plugging or clogging.

WATER USE EFFICIENCY

The previous sections discussed the engineering aspects of irrigation efficiency. Irrigation efficiency is clearly influenced by the amount of water used in relation to the irrigation water applied to the crop and the uniformity of the applied water. These efficiency factors impact irrigation costs, irrigation design, and more important, in some cases, the crop productivity. The water use efficiency has been the most widely used parameter to describe irrigation effectiveness in terms of crop yield. Viets^[16] defined water use efficiency as

$$WUE = \frac{Y_g}{ET} \quad (13)$$

where WUE is water use efficiency (kg m^{-3}), Y_g is the economic yield (g m^{-2}), and ET is the crop water use (mm). WUE is usually expressed by the economic yield, but it has been historically expressed as well in terms of the crop dry matter yield (either total biomass or aboveground dry matter). These two WUE bases (economic yield or dry matter yield) have led to some inconsistencies in the use of the WUE concept. The transpiration ratio (transpiration per unit dry matter) is a more consistent value that depends primarily on crop species and the environmental evaporative demand,^[17] and it is simply the inverse of WUE expressed on a dry matter basis.

Irrigation Water Use Efficiency

The previous discussion of WUE does not explicitly explain the crop yield response to irrigation. WUE is influenced by the crop water use (ET). Bos^[3] defined a term for water use efficiency to characterize the influence of irrigation on WUE as

$$WUE = \frac{(Y_{gi} - Y_{gd})}{(ET_i - ET_d)} \quad (14)$$

where WUE is irrigation water use efficiency (kg m^{-3}), Y_{gi} is the economic yield (g m^{-2}) for irrigation level i , Y_{gd} is the dryland yield (g m^{-2} ; actually, the crop yield without irrigation), ET_i is the evapotranspiration (mm) for irrigation level i , and ET_d is the evapotranspiration of the dryland crops (or of the ET without irrigation). Although Eq. 14 seems easy to use, both Y_{gd} and ET_d are difficult to evaluate. If the purpose is to compare irrigation and dryland production systems, then dryland rather than non-irrigated conditions should be used. If the purpose is to compare irrigated regimes with an unirrigated regime, then appropriate values for Y_{gd} and ET_d should be used. Often, in most semiarid to arid locations, Y_{gd} may be zero. Bos^[3] defined irrigation water use efficiency as

$$IWUE = \frac{(Y_{gi} - Y_{gd})}{IRR_i} \quad (15)$$

where IWUE is the irrigation efficiency (kg m^{-3}) and IRR_i is the irrigation water applied (mm) for irrigation level i . In Eq. 15, Y_{gd} may be often zero in many arid situations.

CONCLUSION

Irrigation efficiency is an important engineering term that involves understanding soil and agronomic sciences to achieve the greatest benefit from irrigation. The enhanced understanding of irrigation efficiency can improve the beneficial use of limited and declining water resources needed to enhance crop and food production from irrigated lands.

Abstract

This entry focuses on unique aspects of irrigation-induced soil erosion that are important when managing and simulating soil erosion on irrigated lands. Soil erosion mechanics can be divided into three components: detachment, transport, and deposition. Water droplets and flowing water detach soil particles; flowing water then transports these detached particles downstream; and deposition occurs when flowing water can no longer transport the soil particles because flow rate decreases as water infiltrates or as rill slope or roughness changes. Some particles are deposited within a few meters, although others are transported off the field with runoff water. These mechanisms are the same for surface irrigation, sprinkler irrigation, and rainfall; however, there are some systematic differences between irrigation and rainfall erosion, especially between surface irrigation and rainfall.

INTRODUCTION

Irrigation is important to global food production. About 15% of cropland^[1] and 5% of food production land, which includes rangeland and permanent cropland,^[2] are irrigated. However, irrigated land produces more than 30% of the world's food,^[3] which is 2.5 times as much per unit area compared with non-irrigated production.^[1] In the United States, approximately 15% of the harvested cropland is irrigated; however, almost 40% of the total crop value is produced on irrigated land.^[4]

Although sprinkler- and drip-irrigated areas are increasing, most of the world's irrigated land uses surface or flood irrigation. The countries with the largest irrigated areas are India—59,000,000 ha, China—52,580,000 ha, the United States—21,400,000 ha, and Pakistan—18,000,000 ha.^[2] These countries account for 55% of the world's irrigated land; all other countries have less than 10 million hectares each of irrigated land.^[2] About 50% of the irrigated land in the United States is surface irrigated^[5] although 95% to 99% of the irrigated land in India, China, and Pakistan is surface irrigated.^[6]

Soil erosion from irrigated fields has been discussed previously,^[7,8] and we focus on unique aspects of irrigation-induced soil erosion that are important when managing and simulating soil erosion on irrigated lands. Soil erosion mechanics can be divided into three components: detachment, transport, and deposition. Water droplets and flowing water detach soil particles; flowing water then transports these detached particles downstream;

and deposition occurs when flowing water can no longer transport the soil particles because flow rate decreases as water infiltrates or as rill slope or roughness changes. Some particles are deposited within a few meters, although others are transported off the field with runoff water. These mechanisms are the same for surface irrigation, sprinkler irrigation, and rainfall; however, there are some systematic differences between irrigation and rainfall erosion, especially between surface irrigation and rainfall.

SURFACE IRRIGATION

Soil erosion is often a serious problem on surface-irrigated land (Figs. 1 and 2). Erosion rates as high as 145 Mg/ha in 1 h^[9] and 40 Mg/ha in 30 minutes^[10] were reported in some early surface irrigation erosion studies. These extreme losses do not represent a sustained seasonal rate. Annual soil losses of 1 to 141 Mg/ha from surface-irrigated fields were reported in a 1980 southern Idaho study.^[11] Within-field erosion rates on the upper quarter of a furrow-irrigated field can be 10 to 30 times more than the field average erosion rate.^[12] Some soil eroded from the upper end of a field is deposited on the lower end, whereas some soil leaves the field with runoff. Losing topsoil from the upper end of the field can decrease crop yields 25% compared with the lower end of the field.^[13]

Sediment cannot be transported without runoff. Runoff is planned with many surface irrigation schemes in order to irrigate all areas of the field adequately. Under ideal

Fig. 1 White area in the field caused by erosion from more than 80 years of surface irrigation.

Fig. 2 Eroded irrigation furrows near the inflow end of a field.

conditions, properly designed and managed sprinkler irrigation systems will not have any runoff from the irrigated area. However, economic and water supply constraints, along with variable slope and soil conditions, often force compromises in sprinkler irrigation design.

SPRINKLER IRRIGATION

Runoff is rarely a problem with solid-set sprinkler irrigation systems because stationary sprinklers uniformly apply water at low rates (e.g., 2 mm/h). At the other end of the spectrum are systems with continuously moving laterals (center pivot and lateral move systems), which apply water to smaller areas (5–20 m wide) at higher rates than solid-set systems (e.g., 80 mm/h). Traveling lateral systems must irrigate large fields to reduce cost per unit area; this necessitates high instantaneous application rates to meet crop

water requirements over the entire field. Application rates for center pivot and lateral move irrigation systems often exceed the soil infiltration rate; therefore, runoff is almost always a potential problem. Sprinkler type, nozzle pressure, and nozzle size influence runoff and soil erosion by affecting application rate, wetted area, and droplet size. Low-pressure sprinklers, which reduce energy costs, have smaller pattern widths and therefore greater application rates. Lower pressure also produces larger drops with greater impact energy on the soil.

Sprinkler systems, particularly center pivots, operate on variable slopes and topography. Slope direction relative to the lateral affects how runoff accumulates. If the lateral is perpendicular to the slope direction, runoff will tend to move away from the lateral where water is being applied, allowing water to infiltrate before traveling very far. However, if the slope is parallel to the lateral, runoff can accumulate down-slope and begin flowing in erosive streams. Furthermore, if the lateral is traveling up-slope, runoff will flow onto a previously wetted area, whereas with down-slope travel runoff can flow onto dry soil. These factors are further complicated by wheel tracks from moving sprinkler systems that create compacted channels for water flow.

SURFACE IRRIGATION AND RAINFALL EROSION DIFFERENCES

The most obvious difference between soil erosion from rain or sprinkler irrigation and from surface irrigation is the lack of water droplets impacting the soil during surface irrigation. This fundamental difference is important because droplet kinetic energy affects both erosion and infiltration.^[14] When rain begins, droplets wet the soil surface and detach soil particles; as runoff begins, rills form in wet soil. Water flowing in rills is also exposed to falling raindrops, which affects detachment, transport, and deposition in the rills.

For furrow irrigation, rills are mechanically formed in dry soil before irrigation begins. Water is applied to only a small portion of the soil surface. As water advances down the field, it flows over dry, loose soil on the first irrigation and dry, consolidated soil on subsequent irrigations. Irrigation water instantaneously wets the soil, rapidly displacing air adsorbed on internal soil particle surfaces.^[15] The rapid replacement of air with water breaks apart soil aggregates,^[7] increasing the erodibility of the soil. Preliminary results from a southern Idaho field study showed that soil erosion from initially dry furrows was greater than soil erosion from furrows that were prewet by drip irrigation.

The hydraulics of rill flow from rain differ from furrow irrigation. Rill flow rate tends to increase downstream as additional rain water plus sheet and rill flow combine. During furrow irrigation, flow rate decreases with distance down the furrow as water infiltrates and increases with time as infiltration rate decreases, which changes sediment detachment and transport capacities with distance and time.

The duration of furrow irrigation runoff (typically 12 hours or more) is generally longer than most rain runoff events. Temporal changes in infiltration, soil and water temperature, rill size and shape, and soil erodibility become more important for longer runoff events. Sediment concentration tends to decrease with time during furrow irrigation. Flow rate, however, increases with time, which should increase sediment detachment and transport. This indicates that soil erodibility decreases during furrow irrigation by phenomena such as armoring, surface sealing, or other unrecognized processes.

Predicting small erosion events is important for irrigation. Seasonal irrigation-induced erosion occurs during numerous controlled and often small events rather than during one or two large erosion events. In southern Idaho, e.g., a cornfield may be sprinkler irrigated 15 to 20 times or furrow irrigated 6 to 8 times during the growing season. The magnitude of a single irrigation erosion event is usually much smaller and less dramatic than that of the erosion from a single 50-mm thunderstorm occurring on freshly tilled soil without an established crop. However, the cumulative soil loss from irrigation during the growing season may be substantial.

Chemical quality of rainfall varies less from location to location than surface water and groundwater quality. Irrigation water quality can also vary during the season as return flow is added to surface water sources or as groundwater and surface water sources are mixed. Water quality can significantly impact erosion from furrow- and sprinkler-irrigated fields. Increasing electrical conductivity (EC) tends to decrease erosion, whereas increasing sodium adsorption ratio (SAR) tends to increase erosion.^[16,17] Interactions among EC, SAR, clay flocculation, soil chemistry, rainfall application rate, etc. influence the effects of water quality on infiltration and erosion.

Abstract

Irrigation can be broadly defined as the practice of applying additional water (beyond what is available from rainfall) to soil to enable or enhance plant growth and yield and, in some cases, the quality of foliage or harvested plant parts. The water source could be groundwater pumped to the surface or surface water diverted from one position on the landscape to another. The development of irrigation water often entails the development of large-scale, geographically significant dams and water impoundments and/or diversions that can provide additional functions apart from crop growth enhancement, e.g., flood control, recreation, or generation of electricity. In many cases, sustainable irrigation development requires concomitant development of surface and/or subsurface drainage.

ANCIENT ORIGINS AND IMPORTANCE

Irrigation may be the single most strategically important, intentional, environmental modification humans have learned to perform. While irrigation's impact has not always been as critical to the global agricultural economy and food supply as it is today, it has always had major local impacts and profound historical and social consequences. In the Bible's book of Genesis, we are told that God's creation of humans was accompanied shortly thereafter by His assignment to Adam of the stewardship of the irrigated orchard that was Paradise. The four life-giving water heads of Judeo-Christian Paradise are also mentioned in the 47th sura of the Koran.^[1] Some anthropologists and historians point to the development of irrigation as the catalyst for the interaction of engineering, organizational, political, and related creative or entrepreneurial skills and activities that produced the outcome referred to as "civilization."^[2–5] In the ancient Persian language, the word "abadan," civilized, is derived from the root word "ab," water.^[1] Fundamental differences in social, cultural, religious, political, esthetic, economic, technological, and environmental outlook have been attributed to modern groupings of humankind related to their use of irrigation.^[5]

The earliest archeological evidence of irrigation in farming dates to about 6000 B.C. in the Middle East's Jordan Valley.^[1] It is widely believed that irrigation was being practiced in Egypt at about the same time,^[6] and the earliest pictorial representation of irrigation is from Egypt around 3100 B.C.^[1] In the following millennia, irrigation spread throughout Persia, the Middle East, and westward along the Mediterranean. In the same broad time frame, irrigation technology sprang up more or less independently across the Asian continent in India, Pakistan, China, and elsewhere. In the New World, the Inca, Maya, and Aztec made wide use of irrigation. The technology migrated as far north as the current Southwestern United States., where the Hohokam built some 700 miles of irrigation canals in what is today called as central Arizona to feed their emerging civilization, only to mysteriously abandon it in the 14th century A.D.^[3]

In the ancient world, the level of irrigation sophistication varied from one setting to the next. The differences, however, stemmed mostly from variations in understanding of both large- and small-scale hydraulic principles, as well as the capabilities to construct feats of hydraulic engineering. The Assyrians, for example, built an inverted siphon into the Nineveh Aqueduct 700 years before the birth of Christ, an engineering feat unrivaled until

the 1860 construction of the pressurized siphons of the New York Aqueduct.^[3]

Some ancient irrigation schemes have survived to the present day where geologic, soil, and climatic conditions were favorable and where then-known management principles were adequate for the prevailing conditions. However, some ancient schemes failed. In the Mesopotamian Valley, Syria, Egypt, and other areas throughout the Middle East, there were many cases where the principles of salt management and drainage were insufficiently understood, resulting in eventual permanent impairment of the land.^[1] Siltation of ancient dams and reservoirs is a testament to inadequate soil conservation measures that eventually reduced the productivity of the land as well as destroyed the capacity of reservoirs to provide an adequate supply of water.^[3] Erosion of irrigation channels, in geologically unstable areas like the Chilean deserts, and catastrophic failure of irrigation channels after earthquakes often defeated the best efforts of ancient engineers to maintain water supplies.^[3]

Modern irrigation technology probably began with the Mormon Settlement of the Utah Great Salt Lake Basin in 1847, and their eventual cultivation of nearly 2.5 million hectares irrigated across the intermountain Western United States by the turn of the century. Whereas the relationships between mass, energy, and turbulence of flow were mastered at remarkably high levels of proficiency in ancient cultures, understanding of chemistry and physicochemical interactions of soil and salt-bearing water was relatively meager even into the 19th century.

MODERNIZATION OF IRRIGATION

The mid-19th century marked a conjunction of several ascending areas of scientific learning, including chemistry, physical chemistry, physics, mineralogy, and biology. These were adapted, blended, and applied in important emerging new subdisciplines of soil chemistry, soil physics, plant physiology, and agronomy, whose fundamental principles were to prove essential for sustainable irrigation system design and operation.

In ancient irrigation developments, soils, climate, and water quality were used in more forgiving combinations at some locations than at others. Where seasonal rains provided leaching, where soils were permeable and well drained, and/or where irrigation water had favorable combinations of electrolyte concentrations and specific cations, irrigation has continued to the present day, even without sophisticated management. In other areas, salinization, increased soil sodicity, and elevated water tables have limited the life spans of irrigation schemes or impaired their productivity. As irrigation moved into more marginal settings, with less productive soils, poorer drainage, and greater salinity and sodicity

problems, the success or failure and ultimate longevity of the schemes became more dependent on knowledgeable application and adaptation of scientific principles. America's Mormon pioneers, choosing to settle in a remote salt-impaired desert habitat, were forced of necessity to use trial and error and the enlightened application of all available new knowledge to reclaim their lands from the desert and to practice a sustainable irrigated crop husbandry. They were so successful in their efforts that their approaches to irrigation and salt-threatened arid land reclamation and management provided the guiding principles for the development of irrigation throughout the Western United States from 1902 (with passage of the Reclamation Act) to the close of the 20th century.^[3] The science of irrigated agriculture and arid zone soil science, in general, relied mostly on the foundation and contributions stemming from these mid-19th century origins.^[7] The development of irrigation in the Western United States was further spurred by passage of the Desert Land Act of 1877 and the Carey Act of 1894, which provided land for settlement and governmental infrastructure for development. The first university-level irrigation course is believed to have been taught by Elwood Mead (Lake Mead's namesake) at the Agricultural College of Colorado in Fort Collins, Colorado.^[8] Mead later took positions with the U.S. Department of Agriculture and eventually was a commissioner for the Bureau of Reclamation. Worldwide, many of the practical modern principles of irrigation system design and irrigated soil management can be traced to the lessons learned in the settling of the American West from 1847 to the close of World War II, when the total irrigated area in the United States had grown to 7.5 million hectares.^[6]

Following World War II, irrigation development worldwide entered a heady period of rapid expansion. World populations were increasing, in part because of increased life expectancies resulting from new medicines and use of dichlorodiphenyltrichloroethane to control malaria and other disease-carrying insects. The advances in technology spurred by the First and Second World Wars were being applied to all avenues of life including agriculture. Electrical, steam, and internal combustion power sources became available to pump and pressurize water. New pump designs, the patenting of the center pivot, and other sprinkler delivery systems came together in a few short decades between and immediately following the wars to revolutionize the ability to deliver water.^[7]

EXISTING STATUS

In the United States, Soviet Union, Australia, and Africa, huge government-sponsored programs were initiated in the 1930s, 1940s, and 1950s to build dams for

hydropower, flood control, and irrigation and to encourage settlement and stabilization of sparsely populated frontiers. The worldwide total irrigated area was about 94 million hectares in 1950 and grew to 198 million hectares by 1970.^[9] In contrast, the world total irrigated area grew to only about 220 million hectares by 1990^[9] and to 263 million hectares by 1996.^[10] Not surprisingly, the easiest, least technically challenging, and least expensive irrigation developments occurred first, and more difficult, more technically challenging, and more expensive projects dominate the remaining potential for water development. In some instances, dams and large-scale water development projects have been hampered by poor economies and the instability of the countries in the potential development areas, rather than by the cost or technical challenges per se.

60% of the earth's grain production and half the value of all crops harvested result from irrigation.^[10] Perhaps, most remarkable is the agricultural production efficiency that irrigation provides worldwide. Some 50 million hectares of the earth's most productive irrigated cropland (4% of the earth's total cropland) produces a third of the entire planet's food crop.^[11] Hectare for hectare, irrigated land produces two to two and a half times the yield and three times the crop value per hectare compared with non-irrigated land.^[10,12,13] The irrigated portion amounts to only about one-sixth of the world's total cropped area^[14] and about 5% of the world's total production area, which includes cropland, range, and pasture.^[15] In the United States, most fresh fruits and vegetables in grocery stores come from irrigated agriculture. Beyond survival and economic impact, even our entertainment and esthetics rely heavily on irrigation. Nearly all-garden nursery stock in the United States is propagated and maintained under irrigation and parks, play fields, golf courses, and commercial landscaping are seldom established and maintained without irrigation.

To put the global production impact of irrigated agriculture in perspective, it would require over quarter billion hectares of new rainfed agricultural land (an area equal to the size of Argentina) to supply the average additional production that irrigation's high yield and efficiency provide. Actually, this estimate is conservative. If the land irrigated was no longer irrigated but left in production, its output would be well below the mean of existing rainfed land; this is because the lion's share of irrigation occurs in arid or semiarid environments. Furthermore, additional rainfed land brought into production to replace irrigated agriculture would be well below the existing rainfed average productivity; this is because the rainfed land with greatest yield potential has already been brought into production. A more realistic estimate might be double or triple the quarter billion hectare nominal replacement estimate.

In a world of six billion people, irrigation has become essential by providing another benefit that cannot be

immediately quantified, but which is as important as or more important than production efficiency or economic gain, or even the often uncredited benefits in many irrigation development schemes of hydropower, flood control, transportation, and rural development. The overriding benefit is security—security derived from food production stability. Substantial portions of the world food supply are subject to precipitous and often unpredictable yield reductions owing to drought. Irrigation was a key component of the “Green Revolution” of the 1960s and 1970s, which stabilized food production in the developing world, providing a new tier of nations the opportunity to turn some of their monetary and human resources to non-agricultural avenues of economic and social development. Much of the drop in the rate of increase of worldwide food production relates to the decrease in the rate of irrigation development since 1980.

ISSUES AFFECTING THE FUTURE

Although there are large projects underway or planned for the near future, notably in China, Pakistan, Brazil, Canada, Spain, and Portugal, the equal of the great dam-building era from 1930 to 1970 will likely never be seen again. Much of the development of irrigation has been achieved through exploitation of groundwater or by smaller-scale entrepreneurial surface water developments. In Australia, e.g., with the disastrous deflation of the world wool market in the 1990s, substantial numbers of individual sheep stations ceased raising animals and developed their surface water supplies to grow vast hectares of irrigated cotton and rice.

Worldwide, further expansions in irrigated area are unlikely to be large because of the limited remaining surface water sources to exploit and because of the growing environmental concerns, especially related to soil water-logging, salinization, and sodication problems. Future increases in irrigated area will likely result mainly from the development of the so-called “supplemental” irrigation in humid rainfed areas; from improvements in water use efficiencies associated with the utilization of existing irrigation resources; and from improvements in the reuse of municipal, industrial, and agricultural wastewaters. Howell^[10] noted that improved efficiencies have resulted in a reduction in the mean applied depth of water in the United States from about 650 mm annually in 1965 to 500 mm. These increased efficiencies have come in great part from the improved understanding of the energy physics of water, which led to modern evapotranspiration (ET) theory and ET-based crop irrigation scheduling.^[9,10] Many other water conservation practices were developed in the last half of the 20th century, including drip and micro-irrigation, which have spread from the hyperarid conditions of Israel in the early 1950s^[11] to nearly every climate and rainfall environment where there is a need, for one reason or another, to conserve water.

Loss of productive capacity caused by soil salinization, sodication, and waterlogging, as well as by runoff contamination, riparian habitat impairment, and species losses, is often cited by critics of irrigation as evidence of fundamental drawbacks of irrigated agriculture. Surveys have indicated that of the existing irrigated lands, some 40–50 million hectares show measurable degradation from waterlogging, salinization, and sodication.^[16,17] Erosion and sedimentation of reservoirs and channels caused the failures of ancient irrigation schemes and have limited the life expectancy of some modern dams to only a few decades as well.^[3,18] These problems should not be trivialized. They demonstrate the need for intensified research and conservation, as well as improved dissemination and the use of known prophylactic and remedial technologies. However, neither should they be overstated nor presented without due consideration of mitigating factors.

If rates of production loss from these problems are weighted by relative yield or economic value of irrigation compared to rainfed agriculture, and if other positive effects of irrigation are considered, the relative magnitude of negative impacts of irrigation is greatly diminished; e.g., runoff contamination from irrigated land would have to be three times the mean for rainfed land, on a crop value basis, or two to two and a half times the mean, on a yield basis, to be “comparable” to problems from non-irrigated agriculture because of the respective relative efficiencies of irrigated agriculture. Both the absolute and relative areas of impaired production, plus the degree of impairment, need to be compared on a global basis to rainfed losses, as well as the potential for remediation and production expansion under either circumstance. Positive impacts of irrigation water development include many social and economic benefits such as hydropower, flood control, transportation, recreation, and rural development. Positive environmental effects result from crops, field borders, canals, ditches, and reservoirs that provide significant expansions of habitat for a variety of wildlife compared to undeveloped arid land.

As with all agriculture methods, irrigated agriculture has greatly improved its ability to provide humanity's essential needs in closer harmony with environmental needs. This is a key priority in modern irrigated agricultural research along with continued improvement in production potential to meet the needs of a growing population. Population growth is occurring mostly in underdeveloped nations, where there is an added expectation of improved diet and standard of living. This expectation raises the need for improved production per capita above a simple linear extrapolation based on population. Only high yield intensive production from irrigated agriculture has shown the potential to meet these projected needs.

The knowledge and technology exist to design and operate irrigated agricultural systems sustainably and without environmental damage or irreversible soil

impairment.^[9,16,19] The problem lies in implementing known scientific principles and technologies in a timely fashion as part and parcel of irrigation project and system design and management. This is true both on a regional or a project basis and at the farm or field level. Politics and economics play pivotal roles in how well-known science and technology are applied. In this respect, irrigated agriculture is no different than the myriad manifestations of rainfed agriculture, or any other environmentally impacting activity. Because of modern political and economic considerations, there is usually great pressure, when designing and developing a large-scale irrigation project, to allocate resources for the development of as many irrigated hectares as possible at the outset. This often occurs without provision of an adequate technical or social support network to the farming community making the transition to irrigated agriculture. Many schemes fail to provide sufficient financial or technical resources to install drainage systems, to educate farmers, or to include them in policy formulation. The resources are needed to help guarantee prudent water application and salinity or drainage management compatible with the social, technical, and financial capabilities of the water users. These are not failures of irrigation. They are failures of human institutions. In this respect, human political, economic, and institutional considerations rather than technical advances or water availability may represent the real challenges for irrigation in the 21st century. These obstacles must be overcome if irrigated agriculture is to provide the production advantage required to satisfy future human needs and to meet improved dietary and living standard expectations.

Irrigation: Soil Salinity

James D. Rhoades

Agricultural Salinity Consulting, Riverside, California, U.S.A.

Abstract

Irrigation has resulted in considerable salination of associated land and water. Surviving the salinity threat requires that the seriousness of the problem be recognized more widely, the processes contributing to the salination of irrigated lands be understood, effective control measures that will sustain the viability of irrigated agriculture be developed and implemented, and that practical reclamation measures be implemented to rejuvenate the degraded lands.

INTRODUCTION

Irrigation is an ancient practice that predates recorded history. While irrigated farmland comprises only about 15% of the world's total farmland, it contributes about 36% of the total supply of food and fiber, and it stabilizes production against the vagaries of weather.^[1] In 30-year time, irrigated agriculture is expected to have to supply 50% of the world's food production requirements.^[1] However, irrigation growth has actually slowed to a rate that is inadequate to keep up with the projected expanding food requirements.^[1] Furthermore, irrigation has resulted in considerable salination of associated land and water. It has been estimated variably that the salinized area is as low as 20% and as high as 50% of the world's irrigated land.^[2–4] Worldwide, about 76.6 Mha of land have become degraded by human-induced salination.^[3] It has been estimated that the world is losing at least 3 ha of arable land every minute to soil salination (about 1.6 Mha per year) and then only to erosion as the leading worldwide cause of soil degradation.^[5–7] These data imply that the rate of salinization in developed irrigation projects exceeds the rate of irrigation expansion.^[8]

Surviving the salinity threat requires that the seriousness of the problem be recognized more widely, the processes contributing to the salination of irrigated lands be understood, effective control measures be developed and implemented that will sustain the viability of irrigated agriculture, and that practical reclamation measures be implemented to rejuvenate the degraded lands.^[9,10]

DELETERIOUS EFFECTS OF SALTS ON PLANTS, SOILS, AND WATERS

Salt-affected soils have reduced the value for agriculture because of their content and proportions of salts, consisting mainly of sodium, magnesium, calcium, chloride, and

sulfate and secondarily of potassium, bicarbonate, carbonate, nitrate, and boron. Saline soils contain excessive amounts of soluble salts for the practical and normal production of most agricultural crops. Sodic soils are those that contain excessive amounts of adsorbed sodium in proportion to calcium and magnesium, given the salinity level of the soil water. An example of a salt-affected irrigated soil is shown in Fig. 1.

Soluble salts exert both general and specific effects on plants, both of which reduce crop yield.^[11] Excess salinity in the seedbed hinders seedling establishment and in the crop root zone causes a general reduction in growth rate. In addition, certain salt constituents are specifically toxic to some plants. For example, boron is highly toxic to susceptible crops when present in the soil water at the concentrations of only a few parts per million. In some woody crops, sodium and chloride may accumulate in the tissue over time to toxic levels. These toxicity problems are, however, much less prevalent than is the general salinity problem.

Salts may also change soil properties that affect the suitability of the soil as a medium for plant growth.^[12] The suitability of soils for cropping depends appreciably on the readiness with which they conduct water and air (permeability) and on their aggregate properties (structure), which control the friability (ease with which crumbled) of the seedbed (tilth). In contrast to saline soils, which are well aggregated and whose tillage properties and permeability to water and air are equal to or higher than those of similar non-saline soils, sodic soils have reduced permeabilities and poor tilth. These problems are caused by the swelling and dispersion of clay minerals and by the breakdown of soil structure (slaking and crusting), which results in loss of permeability and tilth. Sodic soils are generally less extensive but more difficult to reclaim than saline soils.

Beneficial use of water in irrigation consists of transpiration and leaching for salinity control (the leaching requirement). Plant growth is directly proportional to water consumption through transpiration.^[13] From the point of

Fig. 1 Photograph of salt-affected irrigated field.

view of irrigated agriculture, the ultimate objective of irrigation is to increase the amount of water available to support transpiration. Salts reduce the fraction of water in a supply (or in the soil profile) that can be consumed beneficially in plant transpiration.^[14] In considering the use of a saline water for irrigation and in selecting appropriate policies and practices of irrigation and drainage management, it is important to recognize that the total volume of a saline water supply cannot be consumed beneficially in crop production (i.e., transpired by the plant). A plant will not grow properly when the salt concentration in the soil water exceeds some limit specific to it under the given conditions of climate and management.^[11] This is even true for halophytes.^[15] Thus, the practice of blending or diluting excessively saline waters with good quality water supplies should be undertaken only after consideration is given to how it affects the volumes of consumable (usable) water in the combined and separated supplies.^[14]

CAUSES OF SALINATION INDUCED BY IRRIGATION AND DRAINAGE

While salt-affected soils occur extensively under natural conditions, the salt problems of the greatest importance to agriculture arise when previously productive soils become salinized as a result of agricultural activities (the so-called secondary salination). The extent and salt balance of salt-affected areas has been modified considerably by the redistribution of water (hence salt) through irrigation and drainage. The development of large-scale irrigation and drainage projects, which involves diversion of rivers, construction of large reservoirs, and irrigation of large landscapes, causes large changes in the natural water and salt balances of entire geohydrologic systems. The impact of such developments can extend well beyond that of the immediate irrigated area. Excessive water diversions and applications are major causes of soil and water salination in irrigated lands. It is not unusual to find that less than

60% of the water diverted for irrigation is used in crop transpiration.^[9] This implies that about 40% of the irrigation water eventually ends up as deep percolation. This drainage water contains more salt than that added with the irrigation water because of salt dissolution and mineral weathering^[14] within the root zone. It often gains additional salt load as it dissolves salts of geologic origin from the underlying substrata through which it flows in its down-gradient path. This drainage water often flows laterally to lower lying areas, eventually resulting in shallow saline groundwaters of large areas of land (waterlogging). Salination occurs in soils underlain by saline shallow groundwater through the process of “capillary rise” as groundwater (hence, salt) is driven upward by the force of evaporation of water from the soil surface. Correspondingly, saline soils and waterlogging are closely associated problems.

Seepage from unlined or inadequately lined delivery canals occurs in many irrigation projects and is often substantial. Law et al.^[16] estimated that 20% of the total water diverted for irrigation in the United States is lost by seepage from conveyance and irrigation canals. Biswas^[17] estimated that 57% of the total water diverted for irrigation in the world is lost from conveyance and distribution canals. Analogous to on-farm deep percolation resulting from irrigation, these seepage waters typically percolate through the underlying strata (often dissolving additional salts in the process), flow to lower elevation lands or waters, and add to the problems of waterlogging and salt loading associated with on-farm irrigation there. A classic example of the rise in the water table following the development of irrigation has been documented in Pakistan and is described by Jensen et al.^[9] and Ghassemi et al.^[2] The depth to the water table in the irrigated landscape located between three major river tributaries rose from 20 to 30 m over a period of 80–100 years, i.e., from pre-irrigated time (about 1860) to the early 1960s, until it was nearly at the soil surface. In one region, the water table rose nearly linearly from 1929 to 1950, demonstrating that deep percolation and seepage resulting from irrigation were the primary causes. Ahmad^[18] concluded that about 50% of the water diverted into irrigation canals in Pakistan eventually goes to the groundwater by seepage and deep percolation.

The role of irrigated agriculture in salinizing soil systems has been well recognized for hundreds of years. It is of relatively more recognition that the salination of water resources from agricultural activities is a major and widespread phenomenon of likely equal concern to that of soil salination. The causes of water salination are essentially the same as those of soils, where the final reservoir of the discharged salt load is only a water supply in the former case.^[14] The volume of the water supply is reduced through irrigation diversions and irrigation; thus, its capacity to assimilate such received salts before reaching use-limiting levels is reduced proportionately. Only lately has it become apparent that trace toxic constituents, such as selenium, in

agricultural drainage waters can also cause serious pollution problems.^[19]

IRRIGATION AND DRAINAGE MANAGEMENT TO CONTROL SOIL SALINITY

The key to overall salinity control is strict control that maintains a net downward movement of soil water in the root zone of irrigated fields over time while minimizing excess irrigation diversions, applications, and deep percolation.^[20] The direct effect of salinity on plant growth is minimized by maintaining the soil–water content in the root zone within a narrow range at a relatively high level, while at the same time avoiding surface ponding and oxygen depletion and minimizing deep percolation. Combined methods of pressurized, high-frequency irrigation and irrigation scheduling have been developed that permit substantially the desired control to be achieved.^[21,22] These systems transfer the control of water distribution and infiltration from the soil to the irrigation equipment. This results in less excess water (and hence, less salt) being applied overall to the field to meet the needs of a part of the field area having the lowest intake rate, as done in the more traditional gravity irrigated systems. However, gravity irrigation systems can be designed to achieve good irrigation efficiency and salinity control even though surface ponding does occur. The so-called level-basin, multiset, cablegation, surge, and tailwater-return systems are among them.^[21,22] The need for irrigation and the amount required to meet evapotranspiration and leaching requirement is determined from plant stress measurements, the calculations of evapotranspiration amounts, measurements of soil–water depletion, measurements of soil (or soil–water) salinity, or a combination of them.^[21,22]

In addition to effective methods of irrigation scheduling and application, appropriate irrigation and salinity management also require an effective delivery system. Delivery systems have generally been designed to provide water on a regular schedule. Efficient irrigation systems require more flexible deliveries that can provide water on demand as each crop and particular field have need of it. Delivery systems can be improved by lining the canals, by containing the water within closed conduits, and by implementing techniques that increase the flexibility of delivery.

As briefly discussed earlier, irrigated agriculture is a major contributor to the salinity of many rivers and groundwaters, as well as soils. Reducing deep percolation generally lessens the salt load that is returned to rivers or groundwater and their pollution.^[14] Additionally, saline drainage waters should be intercepted before being allowed to mix with water of better quality. The intercepted saline drainage water should be desalted and reused, disposed of by pond evaporation or by injection into some suitably isolated deep aquifer, or better should be used for irrigation in a situation where brackish water is appropriate. Various

irrigation and drainage strategies have been developed for minimizing the pollution of waters from irrigation and for using brackish waters for irrigation.^[14,23] The desalination of agricultural drainage waters is not economically feasible, but improved techniques for doing this exist and some are being implemented. However, more needs to be done in this regard.

Traditionally, the concepts of leaching requirement and salt-balance index have been used to plan and judge the appropriateness of irrigation and drainage systems, operations and practices with respect to salinity control, water-use efficiency, and irrigation sustainability. However, these approaches are inadequate. The recommended method is to monitor directly the root-zone salinity levels and distributions across fields as a means to evaluate the effectiveness of salinity, irrigation, and drainage management practices, to detect problems, to help determine the underlying causes of problems, and to determine source areas of major water and salt-load contributions to the underlying groundwater. Theory, equipment, and practical technology have been developed for these purposes.^[24] More information about irrigation and drainage management to control soil and water salinity is found elsewhere.^[25–27]

Abstract

Shifting cultivation (locally jhum) is a traditional agricultural system and involves slashing of the native vegetation and burning the slash to generate nutrients *in situ* to support the crop cultivation for few years before the area is abandoned. The system is practiced in Eastern Himalayas and represents one of the predominant land uses in the mountainous region of North East India (NEI) covering an area of 1.5 million hectares (Mha). The shifting cultivation has been sustainable because of relatively longer fallow periods. However, the system is outdated and irrelevant because of the population-driven reduction in the duration of the fallow cycle (3–5 years), with the attendant degradation of soil and other natural resources. The annual loss ($\text{Mg ha}^{-1} \text{ yr}^{-1}$) of top soil, nitrogen (N), and potassium (K) under shifting cultivation area in NEI is 58.9, 7.1, and 4, respectively. Soil erosion, nutrient loss, and other ecosystem disservices exacerbated from cultivation with short fallows are jeopardizing the soil resilience and ultimately leading to poverty and food insecurity among the shifting cultivators. Even though a number of alternatives for shifting cultivation (terrace cultivation and agroforestry intervention) have been proposed and experimented upon, little progress has been made in finding viable alternatives. Therefore, this entry aims to develop a comprehensive mechanism that sustains the forest ecosystems and enhances livelihood security of the hill farmers in NEI. This entry proposes feasibility of introducing “grains for forest management program” through provision food grains to farmers as an alternative to shifting cultivation. The proposed program is also envisaged to achieve: 1) soil restoration and strengthening of ecosystem resilience; 2) food security through provisioning of grains under grains for forest management; and 3) carbon offset under climate negotiations.

INTRODUCTION

Shifting cultivation, variously termed as “slash-and-burn agriculture,” “swidden,” and “rotational bush fallow agriculture,” is called “jhum” in India. It practiced in the wet tropics and covers ~30% of the world’s uplands from Africa, Latin America, Oceania, and South and Southeast Asia.^[1] Being the oldest farming system of the world and representing the dominant land use in the mountainous regions of South and Southeast Asia, it involves clearing of mountainous land by cutting the vegetation (tree or bushes), leaving the biomass *in situ* for drying, and finally burning it for production of charred material for soil fertility enrichment. Subsequently, multiple crops (annual and perennial) are grown simultaneously on the same land until soil fertility is depleted, and farmers move to a new forest patch and repeat the cycle.^[2] In sub-Saharan Africa, this traditional

agriculture consists mainly of 1) bush fallow-food crop rotation; 2) permanent tree crop farming; 3) taungya, a form of agroforestry; and 4) permanent compound farming. The latter not only involves food crops but also plants that are known for their effectiveness in restoring soil fertility.^[3] This system embodies the agroforestry concept of combining crops and trees and ensures the dominance of effective tree species during the fallow period.^[4,5] Over the centuries, shifting agriculture has been sustainable with satisfactory yield on a long-term basis.^[2,6] The time difference between two subsequent cultivations on the same land (the jhum cycle), which was more than 20 years,^[2] is reduced to 3–5 years. Such population-driven abrupt decline in jhum cycle leads to accelerated soil erosion, nutrient loss, decline in productivity, and reduction in biodiversity and that ultimately exacerbates ecosystem disservices. Moreover, vicious cycle can lead

to irreversible degradation of soil and a disintegration of the ecosystem (under review Nath et al., 2015). Therefore, sustainability of this old-age subsistence agricultural system is questionable. Terrace cultivation and agroforestry systems were introduced in North East India (NEI) as an alternative to shifting cultivation with little success. Therefore, this entry aims to identify viable alternatives to shifting cultivation, especially those which are ecologically compatible, socially acceptable, economically feasible, and environmentally sustainable. In this entry, shifting cultivation in NEI, part of Eastern Himalaya, a biodiversity hotspot, is analyzed with respect to soil quality as an indicator of sustainability. In addition, a viable alternative for this cultivation system is proposed so that farmers can set aside the fragile ecosystem for restoration and nature conservancy.

SHIFTING CULTIVATION IN NEI

North East India (NEI) comprised of eight states (Arunachal Pradesh, Assam, Manipur, Meghalaya, Mizoram, Nagaland, Sikkim, and Tripura) and covered 26.3 million hectares (Mha) or ~8% of total geographical area of India (329 Mha). NEI is situated at the confluence of Indo-Malayan, Indo-Chinese, and Indian bio-geographical realms. Because of its geographical location, NEI

represents diverse ecosystem types dominated by mountains and is endowed with rich forest resources. There are over 100 different tribes in NEI, differing linguistically and culturally^[2] practicing shifting agriculture for millennia. This agricultural practice has evolved as a part of the culture of the hill people of the region, and the agricultural procedures are closely linked with the sociocultural practices and religious beliefs.^[2] However, increasing population pressure has drastically reduced the jhum cycle and has been the cause of poverty and food insecurity for the hill farmers and environmental degradation in the NEI landscape. Schematic presentation of short fallow cycle in practice and the consequences of this degradative process are presented in Fig. 1. Land area measuring 1.5 Mha is under shifting cultivation in NEI.^[7] An indiscriminate practice of shifting cultivation decreased forest area by ~625 km² over a short period between 2011 and 2013.^[8] During the same period, Nagaland experienced severe deforestation (274 km²) followed by that in Tripura (111 km²), Manipur (100 km²), and Arunachal Pradesh (89 km²).

Soil Erosion and Nutrient Loss

As a large proportion of the mineral nutrients in the tropical ecosystem are stored in the vegetation,^[14,15] slashing and

Fig. 1 Schematic presentation of shifting cultivation 1) with short fallow cycle and 2) with long fallow cycle.

burning appear to be the only way to prepare the land for cultivation to incorporate nutrients into the soil that have been accumulated in vegetation. The effects of slashing and

burning involve changes in soil physical and chemical properties and in nutrient status.^[16,17] The effects of fallow periods on soil physical and chemical properties in

Fig. 2 Schematic representation of effect of fallow periods on soil physical and chemical properties in North East India. Values represent percentage increase or decrease of particular property than that under native climax forest.

Source: From Ramakrishnan,^[2] Ramakrishnan & Toky,^[9] Mishra & Ramakrishnan,^[10] Saha & Mishra,^[11] Grogan, Lalnunmawia, et al.,^[12] and Singh, Bordoloi, et al.^[13]

comparison with native forest in NEI are outlined in Fig. 2. Drastic changes occur in soil macro- (>250 μm) and micro-aggregates (<250 μm) and porosity because of densification under short fallow period. Soil compaction reduces water in soil (θ) and hydraulic conductivity (K_s ; Fig. 2; Table 1). Soil erosion (60–80% more) and surface runoff (80–100% more) are more under short fallow than under native forest. Therefore, vegetation slashing and burning with short fallows deteriorate soil physical properties by disintegrating soil stable aggregates and disrupting continuity of pores from surface to subsurface soil that reduces water infiltration and percolation and increases surface runoff. Soil under short fallow is prone to a high nutrient loss (60–700% more than native forest), resulting into low agronomic yield. Similar to NEI, a study from Zambia indicated decline in maize yield (*Zea mays*) under short fallows.^[32] Changes in soil properties under shifting cultivation in different parts of the tropics are presented in Table 1. These data in Table 1 indicate trends similar to those observed in NEI (Fig. 2). The magnitude of annual losses ($\text{Mg ha}^{-1} \text{ yr}^{-1}$) of top soil, N, and K under shifting cultivation area in NEI may be as high as 58.9, 7.1, and 4, respectively.^[33] Decline in soil fertility leads to decline in crop yields^[6,32,34,35] and forces cultivator to abandon the land and shift to another forest patch and begin the new cycle. Therefore, shifting cultivation with short fallow is the prime driver of poor socioeconomic status of the hill farmers and of the degraded biophysical environment. In contrast, long fallow period improves the soil quality by improving soil structure (Fig. 2). During the long fallow period, changes in soil structure are closely linked with increase in soil organic matter (SOM) and soil humus contents.^[6,15] In NEI, litterfall increased from 1.2 $\text{Mg ha}^{-1} \text{ yr}^{-1}$ during the first-year fallow to 9.7 $\text{Mg ha}^{-1} \text{ yr}^{-1}$ in the 20-year-old fallow,^[36] almost equivalent to the mature forests,^[37] implying a critical role of biomass accumulation in long fallows to soil restoration. In case of older fallow, organic inputs through above- and belowground litterfall and development of macro- and microfaunal population^[38] accelerate the decomposition process and subsequently improve soil quality, and the system slowly approaches to the level of climax forest.

Soil Organic Carbon (SOC) and Shifting Cultivation

The SOC derived from the partially combusted biomass is the basis for maintenance of productivity of soil under shifting cultivation. Nutrients derived from biomass burning are stored in organic form and held in the mineral form on the exchange sites of SOC.^[39,29] In the absence of vegetation cover in the first and second year of cropping phase, SOC generated remains prone to the accelerated erosion. A decrease of 14–20% of SOC in

top soil during the cropping phase of shifting cultivation has been reported,^[29] and it may take up 35 years to regain the content comparable to that under a primary forest.^[39] The oxidative loss of SOC during biomass burning releases CO₂ and, therefore, has positive feedback on global climate change. However, fallow systems apparently regain the SOC content (Fig. 2). A study from Madagascar showed that a longer fallow length supported more mature soil with high

SOC content.^[40] In a Rio Negro watershed, an increase in SOC by 18% was observed after 5 years of fallow period.^[41] Therefore, accretions of SOC with increase in fallow periods are the result of organic matter input from the above- and belowground litter deposited by fallow vegetation.

Proposed Alternative Program for Shifting Cultivation in NEI

Synthesis of data on soil erosion, loss of nutrients, and SOC reveals that a short fallow cannot fulfill the livelihood requirements of the increasing hill populace due to

Fig. 3 Proposed viable alternative for shifting cultivation to set-aside the fragile ecosystem for restoration and nature conservancy in North East India.

severe decline in agronomic yield. Poverty and unavailability of alternate sources of gainful employment drive hill agricultural communities toward unsustainable utilization of even marginal lands. The effect is loss of the soil resilience, leading to the unsustainability of the shifting agricultural system. Sustainability of the fragile ecoregion can be managed through maintaining longer fallow periods, but this also seems to be unachievable due to rise in population and their subsequent livelihood requirement in the form of fuel, food, and fodder. Further, maximizing yield from short-term fallow is not a viable option considering soil degradation and its attendant socioenvironmental problems. Thus, there is a need to develop a comprehensive plan so that forest can be managed on long-term basis and, at the same time, the livelihood requirement of hill farmers is fulfilled. In this context, we propose the introduction of “grains for forest management program” as an alternative to shifting cultivation, where farmers can be provided with food grains that they otherwise grow by shifting cultivation (Fig. 3). Rather than a subsidy, food grains provided are an in-kind payment for ecosystem services (PES) for restoration of degraded lands. India has made commendable success in food grain production with an annual production rate of 264 million metric ton.^[42] However, 10–20% of the total production is wasted annually due to lack of adequate storage facility.^[43] Therefore, implementing “grains for forest management program” in NEI and provisioning food grains are appropriate use of surplus food grains, while restoring degraded soils, strengthening ecosystem services, and earning C credits through PES from soil and ecosystem C sequestration. The establishment of such program will also enable the hill farmers to pursue their traditional semiperennial and perennial crop cultivation understorey of the restoring vegetation. This program will fulfill their food, fodder, and other daily life requirements. Considering the soil C sequestration rate of 0.61–0.64 Mg ha⁻¹ yr⁻¹ with conversion of shifting cultivated area to a fallow land in India,^[9,44] total C sequestration in 1.5 Mha of jhum land in NEI should be around 1 Tg yr⁻¹. Lal^[45] reported the monetary equivalent of inherent cost or societal value of SOC is US\$ 0.13 kg⁻¹. Therefore, societal value of 1 Tg of C sequestered is around US\$ 130 million yr⁻¹. Assuming total number of shifting cultivators in NEI at 443,000,^[46] each family can earn US\$ 294 yr⁻¹. Therefore, the proposed “grains for forest management program” will help in improving the socioeconomic status of the hill farmers practicing the subsistence system of shifting cultivation.

CONCLUSION

Considering the socioeconomic condition of hill farmers, increasing population pressure and decreasing dense

forest cover in NEI proposed “grains for forest management program” may be a viable strategy to restore degraded fragile ecoregion and enhance livelihood security. Implementation of the program will also strengthen the ecosystem resilience of this biodiversity hotspot to offer critical ecosystem services. In addition to SOC, C sequestered in the biomass in successional fallows of restored shifting cultivation landscape can bring additional income to the land managers of NEI in the form of offsetting C credits under climate negotiations. Moreover, the implementation of this program will also lead to achieve United Nations proposed program of reducing the rate of land degradation to achieve land degradation neutrality or zero net land degradation.^[47]

Jhum: Shifting Agriculture

P.S. Ramakrishnan

School of Environmental Sciences, Jawaharlal Nehru University, New Delhi, India

Abstract

The forest farmer in the tropics has managed the traditional shifting agriculture (*slash-and-burn agriculture*, locally known in India as *jhum*), which is essentially an agroforestry system organized both in space and time for centuries. Shifting agriculture is largely confined to the humid tropics of Asia, Africa, and South America, with highly variable Oxisols, Ultisols, Inceptisols, and Entisols, where the major soil constraint is the presence of some toxic chemicals with low nutrient reserves. Formal ecological knowledge derived through the hypothetico-deductive method—validated traditional ecological knowledge derived largely through societal experiences and perceptions accumulated by traditional societies during their interaction with nature and natural resources—has a strong human element attached to it.

INTRODUCTION

The forest farmer in the tropics has managed the traditional *shifting agriculture* (*slash-and-burn agriculture*, locally known in India as *jhum*), which is essentially an agroforestry system organized both in space and time for centuries. The small-scale perturbations, in the past, ensured enhanced *biological diversity* in the forest, with enriched crop and associated biodiversity, capitalizing on the nutrient released through slash-and-burn. With increasing pressure on forest resources from outside and on population pressure from within, and the consequent declining soil fertility through land degradation, *agricultural cycle* has shortened. It is suggested^[1] that, in the late 1980s, about 500 million people were dependent on shifting agriculture in 90 countries, covering an area of approximately 400 million hectares of tropical forest land area (Table 1). A subsequent forest resource assessment^[2] found that more than 7% of the 1980 forest area underwent change during the period 1980–1990, with more than half of this change due to shifting agriculture, resulting in moderate to severe degradation.

The net consequence is drastic reduction in shifting agricultural cycle, leading to: 1) drastic yield reduction; 2) reduced system stability and resilience, leading to social disruption; 3) biodiversity decline because of weed takeover, biological invasion, and/or eventual site desertification; and 4) substantial carbon dioxide emitted into the atmosphere. All attempts made so far in finding an alternate to shifting cultivation, for want of a holistic approach in dealing with the complex issues, have had little or no impact on the farmer.^[3] It is in this context that an evaluation of ecological impacts and the finding of an acceptable but sustainable solution(s) to the problem become critical.

SOIL FERTILITY AND NUTRIENT BUDGET UNDER SHIFTING AGRICULTURE

Shifting agriculture is largely confined to the humid tropics of Asia, Africa, and South America, with highly variable Oxisols, Ultisols, Inceptisols, and Entisols, where the major soil constraint is the presence of some toxic chemicals with low nutrient reserves.^[4] The complex tropical rain forests are often extremely fragile. First, these forests, which have developed over centuries, often grow on highly infertile soil, with biomass as the chief storage compartment for nutrients. Second, in oligotrophic areas, stability is ensured by the presence of a thick surface root mat, which picks up nutrients released from decaying leaf litter on the mineral soil and pumps these nutrients back into the living biomass before they have the chance to enter the mineral soil. Frequent and large-scale perturbations, as are occurring now, upset this delicate balance in nutrient cycling.

In general, nitrogen (N) and potassium (K), being very labile, are often limiting under many situations. Phosphorus (P) deficiency is a widely reported soil constraint in tropical America, which is further compounded by high P fixation related to soil acidity. There are also other problems related to soil acidity—low availability of calcium (Ca) and magnesium (Mg), often times with aluminum (Al) and manganese (Mn) toxicities.

After clear-cutting and burning of the forest, the ecosystem loses its ability to hold nutrients. Losses occur through the volatilization of carbon (C) and N during the burn. Substantial nutrient losses through wind blowing of ash, runoff, and leaching through water may all occur before adequate vegetal cover builds up, during both the cropping and fallow phases. During the cropping phase, losses also occur through the uptake and removal of

Table 1 Forest fallows (thousands of hectares) under shifting agriculture in the late 1980s.

Region	Closed forest fallows	Open forest fallows
South America and the Pacific	108,600	61,650
Africa	61,700	104,350
Asia	69,250	4,000
Tropical world (total)	239,550	170,000

Source: From FAO/UNEP.^[1]

nutrients through biomass that gets harvested. A reduced cycle length (5 years or less) in many parts of the world has led to a drastic decline in soil fertility under short agricultural cycles imposed on the same site over a period of time (Table 1). Largely herbaceous vegetation that develops under very short cycles of 5 years or so does not help in adequate regeneration of the lost soil fertility.

The rapid regeneration of forest vegetation following clearing and burning reduces nutrient loss and allows a return to the steady state cycling characteristics of mature forests. Although farmers deal with the decline in soil fertility in different ways, a minimum of 10–15 years is required for fallow regrowth in order to recoup most of the soil fertility lost during the cropping phase (Fig. 1). The C sequestration in the system depends largely on the cycle length of these systems,^[1] as also observed in the Indonesian case study.^[5] The N budgeting under different cycle lengths of 15, 10, and 5 years is illustrative of the kind of issues involved (Table 2). During one cropping phase, the agroecosystem loses about 600 kg ha⁻¹ N (the difference between the soil N capital before and after one cropping). With the plot under a 5-year cycle having the same cycle length during the last 20 years, this system had lost 1.28×10^3 kg ha⁻¹ N from its initial capital of $7.68\text{--}6.40 \times 10^3$ kg ha⁻¹. While 10- and 15-year agricultural cycles are long enough to restore the original N status in the soil before the next cropping, it seems unlikely that the 600 kg ha⁻¹ N lost during one cropping could be restored under a 5-year cycle—an observation similar to other nutrients, too,

Table 2 Net change of N (10³ kg ha⁻¹ yr⁻¹) in the soil under jhum in northeast India.

	15-year fallow cycle	10-year fallow cycle	5-year fallow cycle	
			First year crop	Second year crop
Soil pool before burning	7.68	7.74	6.40	5.98
Soil pool at the end of cropping	7.04	7.15	5.98	5.60
Net difference	0.64	0.59	0.42	0.38

Source: From Ramakrishnan.^[3]

such as K. The increased frequency of fire and cropping, with too short a fallow phase, thus results in rapid site degradation.

The first step in site degradation is the replacement of forests by an arrested weed stage. Large tracts of forested lands in the Asian tropics, e.g., are taken over by the grass *Imperata cylindrical* (thatching grass, locally known in the Asian region as “alang-alang”). Exotic weed invasion is yet another major consequence of frequent perturbation under short agricultural cycles in many parts of the world, with consequences for ecosystem processes.^[6] In extreme cases, the end result is a bald, totally desertified landscape^[1] (e.g., northeastern India). The consequence of this is less land area of shifting agriculture and a further shortening of the cycle. Therefore, the success of shifting agriculture is, to a large extent, related to nutrient cycling patterns and processes of the forest fallow phase.

KNOWLEDGE SYSTEMS FOR LAND USE MANAGEMENT

“Formal” ecological knowledge derived through the hypothetico-deductive method—validated “traditional ecological knowledge” (TEK) derived largely through societal experiences and perceptions accumulated by traditional societies during their interaction with nature and natural resources—has a strong human element attached to it. This knowledge needs to be effectively integrated

**Fig. 1** Changes in cumulative quantity of available P and K within a soil column of 40 cm depth under 0-, 1-, 5-, 10-, 15-, and 50-year-old jhum fallows (e.g., g eq/m²).

to ensure the participatory land use development of traditional societies.^[7] Linking ecological processes with social processes is the key issue here.

Thus, e.g., the concept of ecological keystone, an end product of a social selection process, is illustrative of the linkages that exist between the traditional and the formal knowledge systems. Thus, in many areas in northeast India where the landscape is highly degraded, a legume crop of lesser known food value, *Flemingia vestita* (locally known in Meghalaya, India, as “Soh-phlong,” yielding up to 3000 kg of edible juicy tuber), which is socially valued, is used both in space and in time under a 2- to 5-year rotational fallow system. By fixing 250 kg ha⁻¹ yr⁻¹ N, this keystone species ensures the sustainability of these low-input agroecosystems, under conditions of extreme pressure on land under low soil fertility. Using organic residues and manipulating soil biodiversity through socially valued and ecologically important keystone earthworm species, sustainable fertility management has been made possible. It is a patented technology that offers opportunities^[8] for effective fallow management practices.

Nepalese alder (*Alnus nepalensis*), a socially valued species, is another N-fixing tree conserved by traditional societies of northeast India in their shifting agricultural plots. It happens to be a socially significant keystone species. This early successional tree species in the northeastern hill region is conserved by the shifting agricultural farmer, during both the cropping and fallow phases. With its roots nodulated by *Frankia*, this species can fix up to about 125 kg ha⁻¹ yr⁻¹ N and has the potential to recover all the 600 kg of N lost from the system over a 5-year cycle period. It would, otherwise, take a minimum of 10 years of natural fallow regrowth to recover all these N back into the system.

In other words, there is a close connection between the ecological and social dimensions of this validated TEK, and there are implications for fallow management through “incremental pathway” and/or “contour pathway” for agroecosystem redevelopment.^[3,9] Adapting this knowledge to modern scientific inputs is important for community participation in soil fertility management and acceleration of the developmental process itself.

SHIFTING AGRICULTURE AND SUSTAINABILITY

Realizing that sustainable soil fertility management is the key issue for finding a solution to the vexed problem of shifting agriculture-affected areas, two different approaches are possible. If the society under consideration is more “traditional,” an *incremental pathway* is more appropriate to be able to relate to their value system. For others who are less traditional and are ready to make a more drastic departure, the *contour pathway* could be the solution.

Incremental Pathway

Building on traditional technology in an incremental fashion is one of the options for shifting agriculture, at least in the short term. Management of forest fallows^[3] or grass fallows^[10] seems to be an attractive cost-effective solution to the problem, as has been suggested through many studies. Such an approach forms the basis for a major initiative, which aims at redeveloping shifting agriculture in Nagaland in northeast India,^[11] through a participatory process of fallow management in over 5500 replicated test plots in farmers’ fields spread across 1200 villages. The key to the management lies in appropriately constructed village-level institutions that are based on the local value system. In parts of South America (Venezuela), natural secondary forest succession has been suggested as a model to replace traditional shifting agriculture: bean (*Phaseolus vulgaris*), corn (*Zea mays*), sugarcane (*Saccharum officinarum*), and pineapple (*Ananas comosus*) in the first year; followed by woody yucca (*Manihot esculenta*), cashew (*Anacardium occidentale*), or papaya (*Carica papaya*); followed by larger trees such as Brazil nut (*Bertholletia excelsa*) and jackfruit (*Artocarpus* sp.). At another level, the home garden concept could be the model for developing a plantation economy (found in many Asian and Latin American countries).

Contour Pathway

As a possible medium strategy, this type of management acknowledges and works with the ecological forces that provide the base on which the system must be built, while acknowledging the social, economic, and cultural requirements of the farming communities. Working with nature instead of dominating it, this approach seeks active planning, keeping in mind the nature of the background ecosystem. Slope management has long been a major element of farming in the Western Pacific region and in the uplands of the Asian tropics. The Sloping Agricultural Land Technology (SALT) developed by the Mindanao Baptist Rural Life Center in the early 1980s in the southern part of the Philippines is based on planting field and perennial crops in 3- to 5-m bands between double rows of N-fixing trees and shrubs planted on contours for soil conservation.^[12] The crop species and the tree/shrub species could vary. Although SALT technology has been tested successfully in many countries in the Asian tropics, socioeconomic and cultural problems stand in the way of its large-scale acceptance.

CONCLUSION

Involving local communities in managing forestry and non-timber forest product-related activities for cash economy is important, as shifting agriculture cannot be viewed in

isolation from forestry and forest-related activities of local communities. In the ultimate analysis, as a long-term strategy, it may be desirable to have a mosaic of agroecosystem types using all of the pathways just mentioned, along with intensive modern agricultural systems, coexisting with natural ecosystem types, managed or unmanaged. The maintenance of the overall sustainability of the system requires a patchwork mosaic that would, albeit inadvertently, be the best plan for effectively managing natural resources of the landscape, in the shifting agriculture-affected areas.

Land Capability Analysis

Michael J. Singer

*Department of Land, Air, and Water Resources, University of California—Davis,
Davis, California, U.S.A.*

Abstract

The amount of land available for the production of food, fiber, and other necessary products for human sustainability is limited. Land capability systems are designed to help determine appropriate uses and management of available land. Land rating systems for agriculture include those that evaluate the potential for bringing new lands into production and others that evaluate the production potential and conservation needs for those already in production. Additional land capability systems rate lands for non-agricultural uses.

INTRODUCTION

All soils are not the same, and they are not of the same capability for every use. Because the earth's human population exceeds 7 billion on its way to 9 or 10 billion by the mid-21st century, the proper use of land becomes a critical component in human sustainability. Land capability implies that the choice of land for a particular use contributes to the success or failure of that use. It further implies that the choice of land for a particular use will determine the potential impact of that use on surrounding resources such as air and water. To make the best use of land and to minimize the potential for negative impacts on surrounding lands, land capability analysis is needed. The assessment of land performance for specific purposes is land evaluation.^[1] A system that organizes soil and landscape properties into a form that helps differentiate among useful and less useful soils for a purpose is land capability classification (LCC). Land capability is a broader concept than soil quality, which has been defined as the degree of fitness of a soil for a specific use.^[2] Bouma^[3] points out that land capability or land potential needs to be evaluated via various scales and gives the example of precision agriculture, which requires land capability analysis in more detail than that required to determine if an investment should be made to initiate agriculture.

Land capability or suitability classification systems have been designed to rate land and soil characteristics for specific uses (Table 1). Huddleston^[7] has reviewed many of these systems. They may also rate land qualities. Land qualities have been defined by the U.N. Food and Agricultural Organization (FAO)^[1] as “attributes of land that act in a distinct manner in their influence on the function of land for a specific kind of use.” An example of a land quality is the plant-available water stored in soil, and an example of a soil characteristic is the clay content that contributes to the plant-available water-holding capacity.

It is generally recognized that a single soil characteristic is of limited use in evaluating differences among soils,^[15] and that use of more than one quantitative variable requires a system for combining the measurements into a useful index.^[13] Gersmehl and Brown^[16] advocate regionally targeted systems.

KINDS OF SYSTEMS

Land rating systems for agriculture include those that are used to evaluate the potential for agricultural development of new areas and others that evaluate the potential for agriculture in already developed areas, e.g., land capability for grazing in Australia^[17] and fertility capability classification for the tropics.^[18] Many other land capability assessments exist to help planners rate the suitability of agricultural lands for non-agricultural uses (e.g., see Steiner et al.^[19]). Some examples of agricultural land capability systems are described in this entry. All systems have, in common, a set of assumptions on which the analysis is based, and each system answers the question “capability for what use.”

Development Potential

Examples of systems designed to determine the potential for agricultural development include the FAO framework for land evaluation and the U.S. Bureau of Reclamation (USBR) irrigation suitability classification. The FAO framework combines soil and land properties with a climatic resources inventory to develop an agroecological land suitability assessment.

The USBR capability classification was frequently used to evaluate land's potential for irrigation in the Western United States during the period of rapid expansion of water delivery systems.^[4–6,20] It combines social and economic evaluations with soil and other ecological variables to

Table 1 Examples of land capability systems.

System	Purpose	Property	References
FAO framework	Development potential	Used for large-scale development of agriculture	[1,4]
USBR irrigation suitability	Potential for irrigation development	Used for determining potential to repay costs of developing irrigation	[5,6]
USDA LCC	Land capability for agriculture	Uses 13 soil, climate, and landscape properties to determine agricultural capability	[7,8]
SIR	Land capability for agriculture	Uses nine soil and management factors to determine agricultural capability	[9–11]
Soil potential	Soil suitability for specific uses	Uses a cost index to rate land for any potential use	[12]
Soil quality	Determining status of soil profile	Used for determining the status of selected soil properties	[12–14]

determine whether the land has the productive capacity, once irrigated, to repay the investment necessary to bring water to an area. It recognizes the unique importance of irrigation to agriculture and the special qualities of soils that make them irrigable.

Land Capability

The U.S. Department of Agriculture (USDA) LCC is narrower in scope than either the FAO or USBR capability rating systems. The purpose of the LCC is to place arable soils into groups based on their ability to sustain common cultivated crops that do not require specialized site conditioning or treatment.^[8] Non-arable soils, unsuitable for long-term, sustained cultivation, are grouped according to their ability to support permanent vegetation and according to the risk of soil damage if mismanaged.

Several studies have shown that lands of higher LCC have higher productivity with lower production costs than lands of lower LCC.^[21–23] In a study of 744 alfalfa-, corn-, cotton-, sugar beet- and wheat-growing fields in the San Joaquin Valley of California, those with LCC ratings between 1 and 3 had significantly lower input/output ratios than the fields with ratings between 3.01 and 6.^[23] The input/output ratio is a measure of the cost of producing a unit of output and is a better measure of land capability than output (yield) alone. This suggests that the LCC system provides an economically meaningful assessment of agricultural soil capability.

Quantitative systems result in a numerical index, typically with the highest number being assigned to the land or soil with the highest capability for the selected use. The final index may be additive, multiplicative, or more complex functions of many land or soil attributes. Quantitative systems have the following two important advantages over non-quantitative systems: 1) they are easier to use with geographic information system and other automated data retrieval and display systems and 2) they typically provide a continuous scale of assessment.^[12] No single national system is in use, but several state or regional systems exist.

One example of a quantitative system is the Storie Index Rating (SIR). Storie^[9] determined that land productivity is

dependent on 32 soil, climate, and vegetative properties. He combined only nine of these properties into the SIR to keep the system from becoming unwieldy. The nine factors are soil morphology (A), surface texture (B), slope (C), and management factors such as drainage class (X_1), sodicity (X_2), acidity (X_3), erosion (X_4), microrelief (X_5), and fertility (X_6). Each factor is rated from 1% to 100%. These are converted to their decimal value and multiplied together to yield a single rating for a soil map unit as follows^[9–11]:

$$SIR = \left(A \times B \times C \times \prod_{i=1}^6 X_i \right) \times 100 \quad (1)$$

An area-weighted SIR can be calculated by multiplying the SIR for each soil map unit within a parcel by the area of the soil unit within the parcel, followed by summing the weighted values and dividing by the total area as follows:

$$\text{Area-weighted SIR} = \frac{1}{\text{total area}} \times \sum_{i=1}^n \text{SIR soil}_i \times \text{area soil}_i \quad (2)$$

Values for each factor were derived from Storie's experience mapping and evaluating soils in California, and in soil productivity studies in cooperation with California Agricultural Experiment Station cost-efficiency projects relating to orchard crops, grapes, and cotton. Soils that were deep, which had no restricting subsoil horizons, and held water well had the greatest potential for the widest range of crops. Much of what was non-quantitative scoring has been modernized using computer-based decision support systems.^[24]

Reganold and Singer^[23] found that area-weighted average SIR values between 60 and 100 for 744 fields in the San Joaquin Valley had lower but statistically insignificant input/output ratios than fields with indices <60. The lack of statistical significance is scientifically meaningful but may not be interpreted the same by planners or farmers for whom small differences in profit can be significant.

Designers of these systems have selected thresholds or critical limits that separate one land capability class from another. Frequently, little justification has been given for

the critical limit selected. The issue of critical limits is a difficult one in soils because of the range of potential uses and the interactions among variables.^[14]

Soil Potential

Soil potential is an interpretive system that is used for both agricultural and non-agricultural capability assessments. It is an example of a land capability system that is both quantitative and highly specific. Soil potential is defined as the usefulness of a site for a specific purpose using available technology at an indexed cost. Experts in the location where the system will be used determine the soil properties that most influence the successful use of a soil for a particular purpose. The well-suited soils for the use are given a rating of 100. Soil limitations that can be removed or reduced are identified, and continuing limitations that occur even after limitations have been addressed are also identified. The cost of available practices and technologies used to remove limitations and the cost of continuing limitations are indexed, and these index values are subtracted from 100 to yield a soil potential rating for each soil:

$$\text{SPI} = \text{PI} - (\text{CI} + \text{CL})$$

The best soils in an area are those that have the lowest indexed cost for operating or maintaining use, while ensuring the lowest possible environment.

CONCLUSION

All soils are not the same and are not equally capable of sustained use. Various systems have been created that rate soil properties for these uses. Examples include FAO land suitability, USBR irrigation suitability, USDA LCC, SIR, and soil potential. Each has strengths and weaknesses that the user must recognize before using the system.

Land Capability Classification

Thomas E. Fenton

Soil Morphology and Genesis, Agronomy Department, Iowa State University, Ames, Iowa, U.S.A.

Abstract

Land classification may be defined as a classification of specific bodies of land according to their characteristics or to their capabilities for use. A natural land classification system is one in which natural land types are placed in categories according to their inherent characteristics. Some sort of land classification system was used in the transfer of public lands to private owners and users as the United States settled. However, a scientific approach was not possible until soil surveys, topographic maps, economic analyses of production, and other activities became available in the early 1900s. One of the most commonly used land classification systems for land management is the land capability classification. Hockensmith defined this classification as a systematic arrangement of different kinds of land according to those properties that determine the ability of the land to produce permanently. There are three major groupings: 1) capability classes; 2) capability subclasses; and 3) capability units.

INTRODUCTION

A common definition of land is the surface of the earth and all its natural resources. This is interpreted to include the atmosphere, the soil, and underlying geology, hydrology, and plants on the earth's surface.^[1] In the *1938 Yearbook of Agriculture*, land is defined as the total natural and cultural environment within which production must take place. Its attributes include climate, surface configuration, soil, water supply, and subsurface conditions together with its location with respect to centers of commerce and population. It should not be used as synonymous with soil or in the sense of the earth's surface only.^[2] Other definitions included the results of the past and present human activities as well as the animals within this area when they exert a significant influence on the present and future uses of land by man. Thus, the concept of land is much broader than soil. However, because soils are a major component of terrestrial ecosystems,^[3] they integrate and reflect internal and external environmental factors. They have been considered an important factor—if not the major factor—in many land classification systems.

CLASSIFICATIONS

Land classification may be defined as a classification of specific bodies of land according to their characteristics or to their capabilities for use. A natural land classification system is one in which natural land types are placed in categories according to their inherent characteristics. A land classification according to its capabilities for use may be defined as one in which the bodies of land are classified on the basis of physical characteristics with or without

economic considerations according to their capabilities for man's use.^[2]

Olson^[4] defined land classification as the assignment of classes, categories, or values to the areas of the earth's surface (generally excluding water surfaces) for immediate or future practical use. The project, product, or proposal resulting from this activity may be also generally referred to as land classification. Any land classification involves two parts or phases: resource inventory and analysis and categorization. The inventory consists of gathering data and delineating land characteristics on maps. The analysis and categorization put the basic data into a form that can be used generally for a specific use. Thus, there are potentially many land classification systems that could be developed depending on the objectives of the system.

HISTORICAL PERSPECTIVE

Some sort of land classification system was used in the transfer of public lands to private owners and users as the United States settled. However, a scientific approach was not possible until soil surveys, topographic maps, economic analyses of production, and other activities became available in the early 1900s. These sources provided essential data for a scientific approach to land classification. This approach gained added momentum in the mid-1930s due to the need for land classification for many new government programs.

A report submitted to the President of the United States by the National Resources Board dated December 31, 1934,^[5] included a section that dealt with the physical classification of the productivity of the land. The total land area of the United States was rated and divided into five grades

based on the factors thought to affect productivity—soil type, topography, rainfall, and temperature. Norton^[6,7] defined five classes of land in the regions of arable soils according to their use capability. Two other classes were defined for land that should not be cultivated. A National Conference on Land Classification (NCLC) was held in the campus of the University of Missouri in October 1940. The proceedings of this conference were published in the Bulletin 421 of the Missouri Agricultural Experiment Station.^[8] At this conference, it was recognized that land classification in the United States had begun many years prior to 1940. Simonson^[9] summarized the purpose of the NCLC meeting as follows: to encourage and provide opportunity for the discussion of land classification in all of its different aspects.

In the years following the conference, there were many entries published that examined questions related to land classification. General principles associated with technical grouping^[10] or solution of soil management problems^[11] using natural soil classification systems were discussed in detail. Hockensmith and Steele^[12] presented a land capability classification developed for conservation and development of land and for land use adjustments. The system used eight land capability classes with the first four suited for cultivation and the remaining four not suited for cultivation. Within a capability class, the subclasses were determined by the kind of limitation. Within each subclass, the land that required the same kind of management and the same kind of conservation treatment was called a land capability unit. The highest level of abstraction, the capability class, provided a quick, easy understanding of the general suitability of the land for cultivation. Hockensmith^[13] discussed the use of soil survey information in farm planning. A land capability map was an essential part of the farm plan. This map was an interpretative map of the soil map together with other pertinent facts. It was used to help the farmers understand the limitations of their soils and to aid in selection of those practices that would preserve their soils and keep them productive. Klingebiel^[14] defined capability classification as the grouping of individual kinds of soils, called soil mapping unit, into groups of similar soils, called capability units, within a framework of eight general capability classes that were divided into subclasses representing four kinds of conservation problems. This land classification system has been used as a basis for all the conservation farm plans developed by the Soil Conservation Service (now Natural Resources Conservation Service) in the United States since the 1950s and continues to be used. Because of its widespread use, this system is discussed in more detail in the following section.

LAND CAPABILITY CLASSIFICATION

One of the most commonly used land classification systems for land management is the land capability classification. Hockensmith^[15] defined this classification as a systematic

arrangement of different kinds of land according to those properties that determine the ability of the land to produce permanently. Classification was based on the detailed soil survey (scale of 1:15,840 or 1:20,000). The system was described in detail in the Agriculture Handbook No. 210^[16] and continues to be in use, with no significant changes except that Arabic numerals are used to identify the capability classes rather than Roman numerals. There are a number of land capability classifications used throughout the world, but all these methods are patterned after the U.S. system.^[17]

The capability grouping of soils is designed to

1. help landowners and others use and interpret the soil maps;
2. introduce users to the detail of the soil map itself; and
3. make possible broad generalizations based on soil potentialities, limitations in use, and management problems.

There are three major groupings: 1) capability classes; 2) capability subclasses; and 3) capability units. All map unit components, including miscellaneous areas, are assigned a capability class and subclass.^[18]

Capability Classes

The broadest unit is the capability class and there are eight classes. The probability of soil damage or limitations in use become progressively greater from Class I to VIII. There are no additional subdivisions of soils in Class I because by definition the soils in this category have no limitations in use. The proper grouping of the soils assumes that the recommended use will not deteriorate the soil over time.

- Class I soils have few limitations that restrict their use.
- Class II soils have some limitations that reduce the choice of plants or require moderate conservation practices.
- Class III soils have severe limitations that reduce the choice of plants or require special conservation practices or both.
- Class IV has very severe limitations that restrict the choice of plants, require very careful management, or both.
- Class V soils have little or no erosion hazard but has other limitations that are impractical to remove and limit their use largely to pasture, range, woodland, or wildlife food and cover.
- Class VI soils have severe limitations that make them generally unsuited to cultivation and limit their use largely to pasture or range, woodland, or wildlife food and cover.
- Class VII soils have very severe limitation that make them unsuited to cultivation and that restrict their use largely to grazing, woodland, or wildlife.

- Class VIII soils and landforms limitations that preclude their use for commercial plant production and restrict their use to recreation, wildlife, water supply, or to aesthetic purposes.

Capability Subclasses

Subclasses are groups of capability units within classes with the same kind of major limitations for agricultural use. The capability subclass is a grouping of capability units having similar kinds of limitations and hazards. Four general kinds of limitations or hazards are recognized:

1. Erosion hazard
2. Wetness
3. Rooting-zone limitations
4. Climate

The limitations recognized and the symbols used to identify them are risk of erosion designated by the symbol e; wetness, drainage, or overflow, w; rooting-zone limitations, s; and climatic limitations, c. There is a priority of use among the subclasses, if the limitations are approximately of the same degree. The order of use is e, w, s, and c. For example, if a group of soils has both erosion and excess water hazard, e takes precedence over w. However, for some uses, it may be desirable to show two kinds of limitations. This combination is rarely used but when used, the higher priority one is shown first, i.e., *ilew*.

Capability Units

Capability units provide more specific and detailed information than class or subclass. They consist of soils that are nearly alike in suitability for plant growth and responses to the same kinds of soil management. However, they may have characteristics that place them in different soil series or soil map units. Soil map units in any capability unit are adapted to the same kinds of common cultivated and pasture plants and require similar alternative systems of management for these crops. Another assumption is that the longtime estimated yields of adapted crops for individual soil map units within the unit under comparable management do not vary more than about 25%.

CONCLUSION

The grouping of soil map units as used in the land capability classification is a technical classification. The basis for this classification is the natural soil classification system in which the soils and soil map units are defined based on their characteristics and interpretations made based on those properties that affect use and management. For conservation planning, environmental quality, and generation of interpretive maps, it is important to know the kind of soil,

its location on the landscape, its extent, and its suitability for various uses.

Land Evaluation

J. Herbert Huddleston

Department of Soil Science, Oregon State University, Corvallis, Oregon, U.S.A.

Abstract

Soil resource evaluation often serves as a surrogate for land evaluation. In fact, the only real difference between comprehensive land evaluation and soil resource evaluation is that land evaluation may include assessments of social and economic factors, whereas soil resource evaluation includes such factors only in a very general way, if at all.

INTRODUCTION

Land refers to a specific area of the earth's surface that is characterized by its soil, climatic, geologic, topographic, hydrologic, floral, and faunal resources, as well as by the kinds of human activities that take place on it.^[1–4] *Land use* refers to those biological and technological activities that manage and improve land resources for economic and social purposes.^[2] *Land evaluation* refers to an assessment of the properties of the several resources that characterize land as they bear on the requirements of one or more specific land uses.^[3] It is undertaken both to assess the *performance* of land under specified uses^[3] and to *communicate* information about alternative uses of the same tract of land.^[5]

Soil, strictly speaking, is only one of the natural resources that characterize the land resource. But the same set of natural resources that define land also define the environment in which soil forms,^[6] and soil expresses both the integrated effects of its internal properties and the combined effects of its surroundings. Soil resource evaluation, therefore, often serves as a surrogate for land evaluation. In fact, the only real difference between comprehensive land evaluation and soil resource evaluation is that land evaluation may include assessments of social and economic factors,^[3,4,7] whereas soil resource evaluation includes such factors only in a very general way, if at all. Readers who are interested in the comprehensive land evaluation approach will find excellent resources in FAO^[3] and McRae and Burnham.^[4]

HISTORICAL OVERVIEW

Land evaluation in some form has been going on for as long as human societies have been able to observe their environment and adapt their activities to the resource qualities available to them. Over four millennia ago, the Chinese were making soil maps as a basis for taxation and

agricultural management, and the early Romans clearly understood that different regions had different soils, and these differences were manifest in different crop yields.

Land evaluation in the United States began in earnest as the Division of Soils initiated soil surveys to direct agricultural development onto the more productive soils^[8] and the Bureau of Reclamation began classifying land suitability for irrigation development. The Bureau of Reclamation later wrote a comprehensive land evaluation manual^[7] in which all related natural resources, as well as the economic factors affecting the development and use of the land, were assessed. The U.S. Department of Agriculture developed the Land Capability Classification,^[9,10] which was based on an interpretation of soil survey information and defined capability explicitly in terms of limitations to the use of soil and risk of damage to soil when cultivated.

After World War II, soil survey information was used increasingly to develop interpretations for land use planning^[11] and other nonagricultural uses of land.^[12] Specific procedures for making these interpretations are spelled out in the *National Soil Survey Handbook*.^[13] In the 1980s, two new interpretations, namely the soil potential rating (SPR) and the land evaluation and site assessment (LESA) program, were developed, both of which incorporate a degree of economic analysis in their evaluation criteria. SPRs^[13,14] are based on net returns from specific agricultural or non-agricultural uses on specific soils. They are determined by expressing the yield, output, or performance of a soil in economic terms and subtracting from the output value the costs of inputs or management practices needed to achieve the desired output. LESA combines an evaluation of resource quality with an evaluation of various social, cultural, and economic impacts on land use.^[15–17] The land evaluation part is really soil resource evaluation because it is based on SPRs, soil productivity ratings, land capability classes, or some combination of these. Site assessment considers impacts associated with parcel size and shape, access to supporting services and markets, historical or cultural values, and compatibility among adjacent and nearby land uses.

STEPS IN THE DEVELOPMENT OF LAND EVALUATION MODELS

The first and most important task is to *specify the objective* as thoroughly and completely as possible. Land evaluation is always undertaken for some specific land use, and because different land uses require different sets of soil and other resource attributes, the objective must be stated clearly to develop evaluation criteria properly. An important corollary of objective specification is that a land evaluation developed for one specific purpose should not be used as a surrogate to classify land for a different use. Land capability classes, e.g., are neither measures of soil productivity nor classes of agricultural suitability and should not be used in land use planning programs that require evaluations of productivity or suitability.

The second step is to *identify those resource properties that most affect the desired use*. This is best done by assembling a committee of local people—namely farmers, farm service advisers, planners, developers, and realtors—who know both the resources of the area and the issues associated with the intended use. Involving local people ensures that the widest possible range of ideas and issues is represented and gives credibility to the land evaluation system that emerges from the process. The committee should first make a long list of all factors that might influence the land use of interest and then, through discussion and debate, narrow the list to a few important factors that are the least correlated with each other as possible.

The third step is to *develop specific criteria for evaluating the impact of each factor selected*. Land evaluation models may be either qualitative or quantitative, deductively or inductively derived.^[18] Qualitative criteria assign ratings such as good, fair, or poor suitability to soil property characteristics. Quantitative criteria assign numerical ratings on a scale of 10, or 100, to the values associated with each property. Deductive models use actual data, such as crop yields, to create classes of land suitability. Inductive models use the values of various soil properties that are highly correlated with performance to develop empirical ratings of land suitability. In all cases, criteria should be specified as completely as possible to maximize consistency among all users. Soil and landscape complexity, however, may defy absolute prescription of criteria that are applicable to all possible situations, in which case the model should leave some flexibility for users to subjectively determine exactly how a criterion should be evaluated.

The fourth step is to *combine all of the individual factor ratings into an overall evaluation* of land quality for the specified objective. Additive models, multiplicative models, or combination models^[18] may all be appropriate, depending on the objective and the consensus of the committee undertaking the land evaluation. Additive models simply sum up all of the individual factor ratings or subtract them from an ideal score of, e.g., 100. They are easy to use,

but these models risk minimizing the full impact of one or more particularly limiting factors, especially if the model includes a large number of factors. Multiplicative models, which create a product of all individual factor ratings,^[19] do allow single factors to control the overall evaluation, but the final rating generated can be significantly lower than each of the individual factor ratings, even when all factor ratings are high. Combined models capture the advantages of both additive and multiplicative models by using additive techniques to combine property ratings within major factors and then by multiplying major factor ratings to generate the overall rating.

The final steps in the process are to *set thresholds for creating land suitability classes* and to *validate the results of the model*. Setting class limits is another committee effort, and it may be done using overall ratings only, ratings of component factors, or both.^[20] Model validation is necessary to ensure the usefulness and credibility of the final product. Several test cases are selected, all model factors are evaluated, and the committee determines subjectively whether the results are realistic and “make sense.” If not, the model is revised—by adding or deleting factors, changing factor ratings, or adjusting criteria for setting thresholds—and then tested again, until consensus is reached.

ROLE OF SOIL SURVEYS IN LAND EVALUATION AND LAND CLASSIFICATION

Soil surveys are the backbone of any land evaluation system for the following three reasons: 1) soils are essential land resources; 2) soil survey interpretations are often sufficient to meet the land evaluation objective; and 3) soil surveys provide a cartographic base from which maps of resultant land evaluation classes can be made. Two issues must be fully understood to use soil surveys properly for land evaluation: the composition of soil map units and the limitations of scale.

Most soil map units are defined by a single kind of soil. Each delineation of these map units represents a single element of the landscape within which soil properties and behavior are reasonably homogeneous. Because soils are naturally variable, however, each soil-landscape element contains small areas whose soils are different from the dominant soil for which the map unit is named. These areas are called *inclusions*, and their soils are identified in map unit descriptions. The problem is that, although inclusions may behave quite differently from the dominant soil for a given kind of land use, it is a common practice to treat each delineation as though it were composed entirely of the dominant, named soil, classify its land use suitability accordingly, and map it as such. Users must understand that some error is inherent in such interpretive maps and avoid the temptation to assume that, once mapped, all areas shown in a particular land use suitability class are 100% pure.

Most soil surveys used for land evaluation purposes are order 2 or order 3 surveys having scales ranging from 1:15,840 to 1:63,360. Because landscape scale soil variability occurs within meters, order 2 and order 3 surveys necessarily entail generalizations that result in inclusions, particularly in the vicinity of soil boundaries. Some detailed land use planning projects may invoke detailed soil surveys at scales of 1:1200 or 1:4800, which do permit higher degrees of accuracy, but it is more common to enlarge order 2 or order 3 maps to overlay the results of a land evaluation on larger-scale planning or plat maps. This is particularly easy to do when a digitized soil map is brought into a computerized geographic information system, and scales can be changed easily at the click of a mouse. Users must understand that simply changing the scale at which a soil or land evaluation map is displayed does not change its accuracy, and all the inclusions present in the original delineations are still present in their representation at a larger scale.

Soil surveys, when used appropriately with full understanding of their limitations, are excellent tools for conducting land evaluations for many kinds of uses. Many land evaluations can be based entirely on existing soil survey interpretations. Others may be developed by identifying relevant factors, evaluating each one according to precisely specified criteria, combining factor ratings into a land evaluation model, and setting thresholds for land suitability classes. Existing soil surveys may then serve as templates for mapping the results of land evaluation efforts.

Land Forms

Carolyn G. Olson

National Leader Soil Survey Investigations, Lincoln, Nebraska, U.S.A.

Abstract

Landforms are features of the earth that together comprise the land surface. They may be of large features, such as plains, plateaus, or mountains, or smaller features, such as hills, eskers, or hillslopes. There are several ways to describe a landform. Surface form is the most common method of description and includes an analysis of shape factors. Early classification generally falls into the following five categories: genetic, process, size, topographic expression (morphology), and degree of erosion.

INTRODUCTION

Landforms are features of the earth that together comprise the land surface. They may be of large features, such as plains, plateaus, or mountains, or smaller features, such as hills, eskers, or hillslopes. The glossary of geology defines a landform as “any physical, recognizable form or feature of the earth’s surface having a characteristic shape and produced by natural causes.”^[1] A similar definition for landform can be found in almost any geology or geomorphology textbook. The word “landform” is derived from the Old English or Old German word *land* and the Latin *forma*.^[2]

DESCRIPTION AND MORPHOMETRY

There are several ways to describe a landform. Surface form is the most common method of description and includes an analysis of shape factors. Shape is characterized by breaks and changes of slope, directions and angles of maximum slope, and other similar information. A minimum of three parameters are used to describe slope shape: 1) slope length or vertical curvature; 2) slope width or horizontal curvature; and 3) gradient. Slope length is measured by a radial that crosses topographic contour lines at right angles. This dimension is sometimes referred to as a longitudinal profile. Slope width, measured perpendicular to the slope length, parallels topographic contour lines. The curvature or shape of a simple landform such as a hillslope may be defined by a series of forms (Fig. 1). Ruhe represented changes in hillslope curvature by a matrix of nine basic forms.^[4] Huggett added surface flow lines to basic slope shapes,^[5] and Pennock et al. combined curvature with landform elements to identify seven different hillslope positions.^[3]

Since there are hundreds of landforms, it might be useful to choose a commonly recognized landform such as a dune

to discuss some of the aspects of shape. Characteristically, many dunes have a steeper, shorter, leeward side and a longer, lower gradient, or windward side and in cross section have a distinctive asymmetry of slope length. Slope width is dependent on the amount of material composing the dune. The curvature of the windward side is often linear to linear convex and that of the leeward side almost any possible combination of forms. In the case of dunes, each distinctive slope also provides information on the wind direction during formation. The map view on topographic maps and aerial photographs of a barchan dune with its commonly recognized crescentic patterns illustrates its direction of movement. Lancaster provides an excellent series of drawings and photographs illustrating several types of dune landforms.^[6]

The third slope-shape factor is gradient, the angle of inclination of the slope with respect to the horizontal. On a topographic map, it is measured at right angles to the contour lines. Soil scientists measure gradient in percentage. Geologists and engineers generally measure gradient in degrees.

In addition to shape, certain landforms are best described by waveforms which include the dimensions of length, height, and periodicity. Examples of landforms for which waveform description is useful are meander curves and dune fields.

Internal form or structure is often included in a landform description. This is an important distinguishing criterion for the identification of eroded or degraded landforms in which characteristic surface morphology has been obscured. For example, many landforms such as dunes, eskers, or barrier islands are composed primarily of sand. However, the distribution of sands and the cross-bedding in a dune are internal structural elements unique to a landform developed by eolian processes.

The shape and size of a landform are not random. These parameters are determined by the processes that build landforms and by the properties of their materials.

Fig. 1 A matrix of representative hillslope shapes.

Source: From Pennock, Zebarth, et al.^[3]

In the case of a depositional feature such as a dune, the size of the feature is also closely related to the amount of depositional material available during formation. A dune can form that is a few centimeters to several hundred meters in height. The former can occur in the dry bed of a small ditch or in intermittent streams, as the wind blows sandy bed material into dune forms. Dunes in the central deserts of China or the Sahara of Northern Africa are examples of the latter.

Landforms have a natural relationship to each other and to the surrounding landscape. Fractal geometry has been used to produce realistic computer-generated reproductions of landforms.^[7] The mathematical concept of fractal geometry also eliminates the problems associated with the scale of observation. A landform is observed and defined differently by an individual on the ground than is a feature observed from earth orbit.

CLASSIFICATION

There are numerous approaches to the classification of a landform.^[8] A summary of early classification schemes^[9] first presented in the study by Howard and Spock^[10] generally fall into the following five categories: genetic,

process, size, topographic expression (morphology), and degree of erosion.

Features have been classified by size.^[11] Landforms were grouped into numbered orders. First-order relief features included continents and ocean basins. Second-order relief features were tectonic mountain belts, plateaus, and plains, and third-order relief features were erosional and constructional features.

Groups of landforms have been organized into physiographic provinces.^[12,13] The provinces are subdivided into sections and grouped into divisions. Each grouping was based on landforms resulting from a set of similar processes or a succession of processes. Similar regional groupings have been produced for the coterminous United States,^[14–16] and for Alaska.^[17]

A genetic classification, or the mode of origin, has some overlap with descriptive systems because different manner of origin may produce different forms. Examples of genetic systems include the classification of volcanic rocks,^[18] the classification of glacial landforms,^[19,20] and landslide types and processes.^[21]

LANDFORM DEVELOPMENT

Landforms may be erosional or constructional in form, or a composite of both. Most landforms are the products of erosion, but many are formed by the deposition of sediments, by volcanic activity, or by movements from within the earth's crust. Examples of depositional features include dunes, moraines, and spits. Examples of erosional features are water gaps, deflation basins, or arêtes. Lahars, lava plains, and volcanoes result from volcanic activity. The formation of many alluvial fans and subsequent episodes of erosion and sedimentation in the basin and range of the Western United States are triggered by tectonic uplift.

LANDFORMS AND MAPPING

Landforms are part of a continuum of near surface features, soils, and surficial sediments. Bloom^[22] describes a landform in a continuum as a unit of systematic analysis. When mapping, distinctive landform populations need to be delineated. The patterns are identifiable in the field with aids such as topographic maps, aerial photography, geophysical surveys, land use maps, and other available information.

Delineating landforms can sometimes simplify soil mapping. For example, in traversing a hillslope from its summit to its toe, one might recognize several differing soil map units. The sequence may repeat itself on adjacent hillslopes resulting in a predictable pattern of soils that can be related back to a distinctive landform population.

In mapping large tracts of land or in remote areas, it is theoretically possible to systematically subdivide surficial deposits into textural, morphological, or genetic

components. In reality, it is often difficult. Instead, the composition and nature of map unit materials over wide areas are generally inferred from landforms.^[23,24] For example, in flying over a region, drumlins are observed, then drumlins and eskers, then disintegration features, followed by moraines at right angles blocking valleys. If the only advance information one has is that the area had been glaciated, the sequence of landforms becomes the key to interpreting that one is crossing the periphery of a former ice sheet, possibly its maximum extent. One can then map the active zone, the transition to the proglacial, ice-contact zone, and the outer edge of the glacial advance from the landform distribution.

Land Husbandry

Francis Shaxson

Consultant, Dorset, U.K.

Malcolm Douglas

Consultant, York, U.K.

Abstract

Agriculture has not only damaged much land already in use but has also expanded into marginal areas—as a result of population pressure and land scarcity—provoking further the declining usefulness of landscapes for a range of purposes. Almost all the land capable of easy sustainable agricultural use is already being farmed. Therefore the challenge is to enhance and sustain productivity of areas already in use. Improvements in husbandry of land are resulting in rapid expansion of ecologically sustainable types of agronomic, environmental, social, and economic benefits to people in different parts of the world.

INTRODUCTION

Inappropriate management of land in both small and large areas results in declining productivity and/or rising costs, and—especially in countries under the intense climatic conditions of the Inter-Tropical Convergence Zone—in avoidable loss of inputs and water in runoff, water stress in plants, soil erosion, sedimentation, flooding, and related problems. This is particularly serious for the millions of resource-poor rural people in this zone, where there is a strong correlation between environmental degradation, poverty, and insecurity of food and water provision.^[1] Agriculture has not only damaged much land already in use but has also expanded into marginal areas—as a result of population pressure and land scarcity—provoking further the declining usefulness of landscapes for a range of purposes. Almost all the land capable of easy sustainable agricultural use is already being farmed. Therefore the challenge is to enhance and sustain productivity of areas already in use. The holistic “better land husbandry” approach interweaves different specific aspects of management of soil, water, and crops in addressing this, within the constraints and opportunities of diverse natural resource-based livelihood systems.

DEFINING LAND HUSBANDRY

Scope

Much of the failure of past remedial efforts has been a result of their narrow sectoral focus, overreliance on simplistic technical solutions, and concentration on alleviating symptoms rather than addressing real causes.

Experiences in many countries show that improvements in soil properties—notably porosity—resulting from better

husbandry of land enable more efficient use of inputs and increased sustainability of production, with considerable benefits to both people and the environment.

Land husbandry is concerned with maintaining the ongoing usefulness of land for chosen purposes and, more specifically, with sustaining the capacity of its soils to support plant growth and—wherever conditions allow—simultaneously to yield water from its catchments. This, in turn, depends not only on adequate levels of organic matter and plant nutrients, but also on the optimum porosity of its soil architecture, whose restoration after degradation, buildup, and continuing stability depends on optimizing and sustaining conditions fit for the transformative actions of its macro-, meso-, and microorganisms.

Because the management of land is undertaken by rural people, good land husbandry has both agro-ecologic and socioeconomic principles.

Meanings

The word “husbandry” is widely understood when applied to animals and crops. As a concept signifying active care for their well-being, it is equally applicable to land. Animal husbandry, crop husbandry, and land husbandry have, in common, the need for the farmer/land user to:

1. understand the characteristics of different types of plants, animals, and land;
2. predict their likely responses to changes in management and to severe environmental events;
3. devise means of strengthening them against damage; and
4. maintain their productivity and usefulness for the chosen purposes (Fig. 1).^[2]

Fig. 1 Three interconnecting husbandries. The farmer is the ultimate decision-maker.

Source: From Shaxson.^[3]

Land husbandry is a broader concept than just “soil-and-water conservation” or land reclamation. Good land husbandry can be defined as: “Care and management of the land to provide outputs of value to the land user and to

society as a whole, while sustaining and enhancing the land’s potentials to continue providing them in the future.”

As a subject for advisers, researchers, and students, “land husbandry” requires integration of disciplines rather than compartmentalization, combining understandings from a range of agronomic, social, environmental, and economic perspectives in ways that acknowledge the land’s ecological nature, and indicate the practicalities of making safe use of it.

Agro-Ecologic Components

Land varies from place to place in a landscape. Different areas of land have different characteristics and different capabilities. Its nature in any place is determined by the particular combination of the features of which it is composed: topography, soil, fauna and flora, and the climate in which it is located.^[4]

Soil stability and productivity derives from multiple interactions between the living and the non-living components of the land, and more specifically from the interactions between its physical, hydrological, biological, and chemical components, under the influences of climate, gravity, and the actions of people. The results may be negative, neutral or—by design—positive in terms of their conservation effectiveness.

Altered hydrology, caused by loss of porosity, and the long periods when bare soil is exposed to the effects of sun, wind, and rain, together with the failure to replenish lost nutrients, are the basic causes of land degradation (Fig. 2).^[5]

Fig. 2 Loss of pore spaces from the soil architecture diminishes the soils’ capacity to accept, absorb, and transmit rainwater, and alters its suitability for growth and functioning of roots.

Source: From Shaxson, Hudson, et al.^[2]

Good land husbandry aims to increase and sustain biomass production—as crops, trees, shrubs, and grasses—by ensuring that there are no avoidable hindrances to soil's acceptance of rain- or irrigation-water nor to its exploration by roots, and that roots are able to access sufficient oxygen, nutrients, and water within the soil. These features also favor both groundwater recharge by rainfall and the regularity of streamflow, as usable water supplies. Minimization of runoff and erosion, and improvements in efficiency of the use of water and other inputs, follow as consequences (Fig. 3).

The total volume, connectedness, and size distribution of pore spaces in the soil architecture (which affect the volume, distribution, and availability of soil water to plants) are greatly improved by the diversity and activity of the various soil organisms that are present—from earthworms, termites, beetles, and so on, down to the soil-inhabiting fungi and bacteria.

After the porosity of soil architecture has been damaged, mechanical or chemical actions cannot provide self-sustaining remedies. In almost all soils, these are only possible via biological actions, which therefore form the true basis of sustainability of stable productive land uses year by year (Fig. 4).

Fig. 3 The condition of the upper layers of the soil determines the partitioning of rainwater between infiltration and runoff, thus affecting the proportion of rainfall that becomes soil water, and affecting the streamflow regime.

Source: From Shaxson.^[3]

Other key concepts in the approach include:

1. plant growth and yields are reduced more directly and rapidly by a shortage or excess of soil water than they are by a loss of soil particles; therefore there should be first emphasis on rainwater management, and improved soil porosity, more than on conservation of soil per se;
2. minimizing runoff (by enabling infiltration) should precede the controlling of its overland flow; therefore agronomic features that manage rainwater's energy are potentially more effective than mechanical measures for limiting soil loss;
3. because of organic matter's multiple beneficial effects—most importantly for biotic activity, water relations, and nutrient relations in the soil—improvement in the amount and management of organic matter is the key to maintaining soil productivity;
4. only after farmers have made improvements in the biological, physical, and hydrological properties of their soils can they expect to obtain the full benefits to their crops from supplying the soil with any additional nutrients in mineral fertilizers.

The starting point for good land husbandry is to characterize the particular area of land with respect to its topography, the nature and condition of its soils, and the likely hazards of degradation attending its use. On this basis, the physical layout and management of the chosen land uses should conform with the land's biophysical characteristics, and the hazards should be counterbalanced by the adoption of conservation-effective husbandry practices.

Fig. 4 Clods from two adjacent plots of a farmer's trial. That from the plot under several years' zero tillage (left, held sideways) shows the residues of previous crops in the process of transformation into soil organic matter, evidence of worms' activities, and good porosity. That from the plot under conventional annual disk-tillage for land preparation (right) has never been protected by crop residues, and shows less darkening by organic matter, less evidence of organisms' activities, and poorer porosity.

Source: Photo by F. Shaxson.

In the tropics and subtropics in particular, for greatest sustainable improvement in productivity, the most important aspects of conservation-effective farming are:

1. maintaining an even surface cover—of at least 30%—of plant materials, particularly crop residues and cover crops;
2. choice of appropriate crop rotations; and
3. no mechanical soil disturbance except that necessary for direct seeding or planting of the crop.^[6]

Synergistic benefits are obtained, in both sustaining soil productivity and enhancing farm livelihoods, through combinations of locally appropriate practices that improve management of rainwater, organic materials, nutrition, and plants, and proactively avoid soil damage.

Socioeconomic Components

Farmers are primarily concerned with stable and economic production, not with the conservation of soil and water per se. They are only likely to adopt and adapt recommendations for better land husbandry if they judge them to be capable, singly or jointly, to:

1. stabilize or increase output;
2. be economic;
3. confer other benefits that are important to them; and
4. simultaneously release resources—time, energy, cash, and so on—for additional favored actions or investments.

Rural people make rational decisions within the “envelope” that bounds their circumstances, as defined by their skills and resources, and by other internal and external potentials and limitations. Improvements in land husbandry are more likely to occur if the “shape” of this envelope is changed and enlarged, than if attempts are made to change their rationality within an unaltered envelope.

These considerations indicate the need for “bottom-up” rather than “top-down” participation with farmers and interchange of information, and for development of the credibility of advisers in the minds of the land users.

Using our ability to foresee land’s reactions to changes, it is possible to assist land users—having the central role as stewards and managers of their soil, water, and vegetation resources—to choose and implement combinations of land use enterprises and active management matching the land’s characteristics, with conservation-positive results in terms of productivity and sustainability.^[7,8]

Central to the promotion, realization, and spread of better land husbandry is the adoption of:

1. people-centered learning approaches, involving field-based discovery exercises through “Farmer Field Schools”;

2. community-based approaches to land management that empower communities to assess the status of their natural resources and to plan, implement, and monitor results of land husbandry improvements; and
3. market-oriented approaches that encourage better land husbandry as the basis for raising productivity and profitability of specific land use enterprises.

BENEFICIAL EFFECTS

There is a growing body of evidence from many countries across the world that improvements in land husbandry resulting in microscale positive effects on land’s productivity also result in benefits at macroscale, both to the environment and to people. The range and size of the derived benefits depend on the nature, degree, and duration of the improvements to the soil conditions.

Table 1 was compiled from reports, from researchers, advisory workers, government agencies, project evaluators, and from farmers’ own observations, of the effects of conservation-effective farming. They come from high-rainfall (1600 mm) to low-rainfall (300 mm) areas, from many countries (including Australia, Brazil, Burkina Faso, Chile, Costa Rica, El Salvador, Honduras, India, Italy, Kenya, Morocco, Niger, Pakistan, Paraguay, and Zimbabwe).

On this basis, comparable effects of such improvements may reasonably be expected elsewhere—in different mixes and to different degrees, according to the particular agroenvironmental and socioeconomic circumstances—where farmers’ balancing of likely risks, costs, and benefits in their particular situations suggest it is worthwhile to adopt. Interchange of information between enthusiastic farmers has proved to be the most effective means of spread.

The most complete expression of the range of multiple effects of improvements in land husbandry is seen in Brazil, where mulch-based rotational zero tillage systems are being implanted on increasingly large areas—e.g., from 1000 ha in 1972 to 14 million ha by 2000. Other countries have experiences of comparable nature, although often of lesser range; but all validate the overall thesis and highlight the urgent necessity to encourage widespread practical application of the principles of better land husbandry in locally appropriate ways.^[6,9]

IMPLICATIONS

Introduction of small or less complex improvements in land husbandry may be relatively straightforward. However, achieving the fullest synergistic and mutually supporting effects of more comprehensive benefits of

Table 1 Direct and derived benefits following better land husbandry.

Better land husbandry	Physical planning		National policy and strategy
+Cover +organic matter, +nutrients ▼ Improved porosity ▼			
For plant	For farm family	For catchment/community	For society
Less destructive impact of rainfall (vertically) and runoff (laterally)	Increased use-efficiency of rain and other inputs	Less damage by floods and sedimentation	Less “greenhouse” gas
Reduced soil loss (e.g., –90%)	Reversal of slow yield decline	Greater recharge of groundwater and regularity of streams' base flow	More carbon fixed
Less direct evaporation from soil surface	Less severe effects of common storms	More water available for irrigation	Less pressure to clear forests for farms' expansion
More biological activity	Yield variations smoothed	More secure dry-weather water supplies	Hydropower supplies maintained
More cation exchange capacity	Reduced costs (e.g., –30%) and increased returns (e.g., +30%)	Less disruption of transport routes	Options retained for a range of land uses in future
More stable aggregates	Less need for irrigation	Reduced costs of infrastructure repairs	etc.
Better pore space	Greater financial resilience re markets, weather	Less pollution of water and soil	
Better aeration in root zone	Greater security of daily food, water	Reduced costs of water treatment	
More water into soil (e.g., +40%)	Less fuel and energy needed	More community cohesion and interest in managing surroundings	
More plant-available water	More flexible timing of operations	etc.	
Prolonged availability to plants of water and nutrients	More diversity possible	Leads to next column ►	
Better soil T^o regime	Improved nutrition and health		
Better root exploration and function	Safer use of sloping lands		
Better growth and yield of biomass (e.g., +30% or more)	etc.		
Soil continually forms top–downward etc.	Leads to next column ►		
Leads to next column ►			Positive support justified!

Feedback	Feedback	Feedback	Feedback

conservation-effective farming over significant areas requires development of local and national policies and strategies both for overcoming constraints and for facilitating adoption and adaptation to fit the various circumstances.^[10] Zero-tillage systems should not be seen as a “quick fix” solution.^[11]

Range managers, agronomists, hydrologists, farm economists, soil scientists, ecologists, geographers, and other

professionals need to link in “an ecology of disciplines” to provide sound advice and appropriate skills that marry the land users’ needs with the land’s characteristics.

By reassessing a common view of land degradation, it is possible to see that attention to increasing cover over the soil, increasing organic matter levels, balancing nutrient supply, and restoring porosity to the soil provides a way of engaging collaboratively with farmers

Fig. 5 (A) In pedological terms, this soil is about 2 m deep, but compaction induced by annual disk-tillage has reduced its effective depth to about 5 cm. This has resulted in severe runoff and soil loss. (B) The roots of this soya seedling show the effects of the compaction on their growth.

Source: Reproduced photo of “Roots of Soybeans” from FAO Bulletin no. 75, 1999 and both photos by F. Shaxson.

in countering the consequences of deforestation, excessive cultivation, and overgrazing, by emphasizing the positive effects of bringing soils alive again, rather than invoking the negative effects of punitive (and usually ineffective) legislation (Fig. 5).^[3]

CONCLUSION

Improvements in husbandry of land are resulting in rapid expansion of ecologically sustainable types of agronomic, environmental, social, and economic benefits to people in different parts of the world. As an indicator, Fig. 6A shows a field at a cereal experiment station near Foggia, Italy, planted with Durum wheat. The left side

Fig. 6 (A) The field planted to Durum wheat at the cereal experiment station near Foggia, Italy. (B) The yield of the ZT plot (left side) subsequently was equivalent to 2.63 t/ha at 15.5% protein; that of the conventionally tilled plot was 2.11 t/ha at 11.4% protein.

(slightly darker) had been under zero tillage, with crop residues left on the surface, for 3 years. The right-hand side had been under conventional tillage for at least that long. Fig. 6B shows the striking difference between representative ears of wheat—that on the left (zero tillage area) evidently was still drawing on available soil water sufficient for the plant to continue photosynthesizing and filling the grain; by comparison, that on the right indicates that exhaustion of a lesser volume of plant-available soil water had seriously limited the time during which grain-filling could occur.

It is increasingly being recognized and demonstrated that an integrated approach is needed for reversing the decline in the productive potentials of land—in both tropical and less severe climatic zones—thus increasing its capacity to produce plant materials and usable water on a sustainable and regular basis.^[12] The indications are that optimizing the husbandry of land provides an essential basis for addressing the problems of hunger and rural poverty.

The subject of land husbandry provides a conceptual matrix within which fit other topics described in this Encyclopedia.

Land Restoration

Richard W. Bell

School of Environmental Science, Murdoch University, Perth, Western Australia, Australia

Abstract

Land is a finite resource. Every attempt must be made to prevent or minimize land degradation. In addition, restoration of already degraded land needs to be undertaken. Land restoration is a relatively new science that is increasingly informed by the emerging discipline of restoration ecology. Land restoration occurs at a range of different scales. Mine rehabilitation has developed many successful practices of land restoration at a site-specific scale. Most success at both regional and landscape scales has been concerned with restoring key ecosystem functions such as nutrient cycling and water balance.

INTRODUCTION

Soils are essentially a finite and nonrenewable resource^[1] but are subject to various forms of degradation. Monographs by Lal and coworkers^[1–3] and papers therein have dealt in depth with soil and land degradation processes and their measurement, impact, and management. Conacher and Conacher^[4] define land degradation broadly as “alteration to all aspects of the natural (or biophysical) environment by human actions, to the detriment of vegetation, soils, landforms and water (surface and subsurface, terrestrial and marine) and ecosystems.” The challenge for sustainable use of land resources embraces both the minimization of the degrading processes and the restoration of previously degraded land. In this entry, the author focuses on restoration of degraded land from a biophysical perspective.

The term restoration is used in this entry as a generic term after the usage of Hobbs and Norton^[5] who suggest “that restoration occurs along a continuum and that different activities are simply different forms of restoration.” Given that part of this entry also concerns restoration of land degraded by mining, the term rehabilitation as defined by Aronson et al.^[6] is also appropriate. Restoration will usually focus on restoring ecosystem functions such as nutrient cycling, hydrological balance, and ecosystem resilience (see the entry *Restoration Ecology*, p. 1932) although restoring the original flora may on occasions be a realistic and appropriate goal. Reclamation is the term that describes the replacement of ecological functions by planting a different vegetation to that which previously grew; it is commonly used in the United States.

LAND RESTORATION PRINCIPLES

Land restoration comprises the following components: determination of end land use, determining the main

limiting factors for restoration and means of alleviating them, and finally planning and implementation of the restoration program. This entry will deal mostly with the first two of these components.

End Land Use

A clear definition of the end land use is a prerequisite for effective restoration of highly disturbed land. This will determine the stakeholders, the scope for restoration, and the key constraints that have to be alleviated and help to define the goals for determining success. End land use has a major bearing on the degree of difficulty of the task of restoration and hence its cost. Restoration of a complete ecosystem, and its function, is a markedly more complex task than restoration of a stable surface or creating a pasture for low intensity grazing.^[5] The former may require decades of systematic research before restoration goals can be reliably accomplished and demonstrably sustainable.

Prior land use and existing use of the surrounding areas will generally determine the end land use except where the substrate or landscape is so radically altered by degrading processes as to make this impossible. Apart from restoring natural ecosystems, agriculture, forestry, housing, industry, amenity and recreation, wetlands, and waste disposal are all possible end land uses.^[7] Economic and sociopolitical factors have a major bearing on end land use, particularly on production lands, in protected landscapes, and in densely settled areas.

While setting end land use is necessary in order to develop tangible goals for restoration, there are also merits in an adaptive rather than a prescriptive approach. As practice improves, new benchmarks for completion can be set, and new possibilities for end land use emerge, as shown in

Table 1 Biophysical factors limiting land restoration, their consequences for site stability and plant growth, and common treatment methods.

Factor	Constraint	Consequence	Treatment
Climate	Drought	Failure to germinate, poor emergence or establishment, plant death	Irrigation, drought tolerant species, adjust time of sowing
	High temperature	Poor germination and emergence, plant death	Mulching
	Low temperature/frost	Delayed emergence, plant death, poor seed set	
	Extreme rainfall/wind events	Water or wind erosion episodes	Contour banks, soil cover by foliage, mulch or stubble, wind breaks
Landform	Slope	Land slippage, soil creep	Deep rooted plants, reshape to lower slope, contour banks, engineering design
	Runoff	Water erosion	Contour banks, reshape to lower slope
	Exposure	Drought, high winds, extreme temperatures	Tolerant plant species
	Aspect	High winds, extreme temperatures	Tolerant plant species
Hydrology	Runoff	Erosion, waterlogging, flooding	Contour banks, increased drainage intensity
	Limited profile water storage	Drought, runoff, increased groundwater recharge	Tolerant plant species, deep ripping
	Groundwater discharge	Water-filled voids, acid mine drainage	Containment of water, wetland treatment ponds
Substrate properties	Acidity	Poor plant growth especially roots, plant death	Lime, acid tolerant species, P fertilizer
	Alkalinity	Poor plant growth, plant death	Gypsum, leaching, alkaline-tolerant species, acidifying materials
	Salinity	Poor plant growth, plant death	Leaching, salt tolerant species, drainage
	Sodicity	Soil dispersion, crusting, poor seedling emergence, erosion	Gypsum, leaching, organic matter addition
	Nutrient deficiency	Poor plant growth	Fertilizer
	Metal toxicity	Poor plant growth, plant death	Lime, tolerant species, phytoremediation
	Low water availability	Poor plant growth, plant death	Irrigation, mulching, organic matter, deep ripping
	Waterlogging	Poor plant growth, plant death	Drainage, tolerant plant species
	Poorly structured soils	Crusting, poor water holding capacity	Mulching, organic matter, gypsum
	Mycorrhiza	Poor plant growth, nutrient deficiency	Topsoil management, inoculation of nursery plants
	Rhizobium	Nitrogen deficiency	Topsoil management, inoculation
	Soil microbes	Poor mineralization of soil organic matter	Topsoil management

the changes with time in bauxite mine rehabilitation in Southwest Australia.^[8]

Problem Diagnosis and Definition: Biophysical Factors Limiting Land Restoration

Land degradation has many different forms and hence different consequences for restoration.^[3] Diagnosing the main form(s) of degradation at a site or in a landscape is a prerequisite for appropriate land restoration. The main biophysical factors limiting land restoration are as follows: climate, landform, hydrology, substrate properties, and plant establishment. These are described briefly later (see also Table 1). Many examples of their

importance and treatment can be found elsewhere in this encyclopedia.

Climate sets the underlying growing conditions for plants in land restoration and in a broad sense determines the range of species able to survive and grow in a particular location. Landform is a prime consideration in restoration because of the need to achieve slope stability and effective erosion control. The important components of landform that limit restoration are slope angle, elevation, aspect, and drainage. Any clearing or significant disturbance of vegetation alters hydrology. Increased runoff is usually the first on-site response, followed by erosion, and then downstream consequences such as flooding. Other changes in hydrology include

altered profile water storage and increased groundwater recharge.

Substrate Properties

Physical properties: Land degradation often alters the soil physical conditions in ways that decrease its suitability for plant establishment and growth, particularly by changing water storage and availability. Water erosion may strip away topsoil; decrease soil depth; and expose subsoil material with different texture, lower organic matter levels, and poorer soil structure. Wind erosion selectively removes clay and humus from the soil surface, increasing the prevalence of coarse materials. Sand deposits from wind erosion may bury topsoil and vegetation.

Chemical properties: Nutrient levels, acidity, alkalinity, salinity, sodicity, and toxic metals and organic compounds are the chemical factors in soils and substrates that can limit plant growth and therefore hamper effective land restoration. Deficiencies of nutrient elements can be diagnosed or predicted by several means.^[9] Once identified, deficiencies can generally be corrected by fertilizer application. The selection of plants with high tolerances of the toxicities from acidity or heavy metals is often the most cost-effective strategy of revegetation even if it means planting a different species mix to that which existed before disturbance.^[10] However, the preferred modern practice in mining is to identify adverse materials and selectively place them in waste dumps where there is no contact with the root zone.

Biological properties: Mining activities and topsoil storage have quite profound negative effects on microbial biomass and activity.^[11] Restoration of microbial biomass may take 7–10 years on revegetated mine sites. Careful handling and reuse of topsoil can often minimize the problems associated with decreased biological activity of soil after land restoration. Maximum activity is retained if topsoil is reused immediately without a period of storage.

Plant Establishment

The prerequisite for effective plant establishment is to ameliorate substrate conditions most likely to limit plant growth. In mining, the aim is to plan mine operations, so that the most benign materials are placed on top of surfaces to be revegetated. This minimizes the need for expensive amelioration of adverse soil conditions.

Plant establishment relies on three strategies, either individually or in combination. Topsoil spreading will often be the most reliable strategy if it is available because it contains seed native to the area, adds soil organisms, and creates a seedbed for seed germination and establishment. However, in some plant communities, seed is stored in the plant canopy rather than in the soil. For the restoration of

these communities, cutting branches and spreading them on the soil surface have proved effective. Nursery-raised seedlings will generally be reliable for plant establishment but are relatively expensive. In addition, there are often many species that are difficult to propagate from seed in the nursery, or they generally regenerate by vegetative means. Direct seeding is usually cheaper than other options although there is significant cost associated with the collection of native seed. Establishment of seedlings especially from direct seeding is hampered by weed competition and grazing by herbivores.

Sustainability

After plant establishment, some measure of the success of restoration is needed. According to Hobbs and Norton,^[5] the following ecosystem characteristics should be considered when setting goals for land restoration: composition, structure, pattern, heterogeneity, function, species interactions, and dynamics and resilience. This raises the need for reliable low-cost indicators of success.^[11] Most indicators have relied on composition and structure of vegetation. Microbial biomass has been advocated as an indicator of nutrient cycling functions. Indicators for pattern, heterogeneity, dynamics, and resilience are less advanced in their development, in part because few land restoration activities have run for long enough to measure these characteristics let alone develop indicators for them.

CONCLUSION

Land is a finite resource. Every attempt must be made to prevent or minimize land degradation. In addition, the restoration of already degraded land needs to be undertaken. Land restoration is a relatively new science that is increasingly informed by the emerging discipline of restoration ecology. Land restoration occurs at a range of different scales. Mine rehabilitation has developed many successful practices of land restoration at a site-specific scale. The challenge ahead is to develop effective land restoration practices at a regional or landscape scale. Most success at both scales has been concerned with restoring key ecosystem functions such as nutrient cycling and water balance.

Abstract

Land, as a fundamental factor in production, has always been integrally related to the economic growth of a country. Until or about the time of the industrial revolution, land resources and their productivity constituted much of a society's wealth. Societies use land differently based on their culture, technology, and political, and economical aspirations. European colonization of the much of the world since Columbus' explorations radically altered global land use. In addition to mineral exploration and mining, the colonial powers introduced new agricultural production systems to serve their political and economic goals. The land use patterns in the developing countries were, to a large extent, determined by the resources and raw material needs of the colonial powers. The soil and climatic endowments and the cultural habits of the people, of course, control the specific land use within a region or country.

INTRODUCTION

There were many events and reasons that resulted in land use changes. It is not the intent here to examine these in detail. The purpose of this entry is to evaluate, on a global perspective, some major changes that took place in the last few centuries and evaluate how these have resulted in the global land use patterns. This entry will focus on agricultural land uses, although it is recognized that increasing urbanization is a serious issue for preserving valuable agricultural land.

ORIGINS OF AGRICULTURE

The term "land use" implies human choices and actions that change and alter the landscape. Initially, agriculture was the main use of the land, and land was valued for its agricultural productivity. Agriculture altered land use in multiple and reinforcing ways. First, humans began altering the land surface as more of it was devoted to growing domesticated plants and raising domesticated animals. Next, agriculture supported an increasing population, which in turn brought more land into production. While

it is true that some hunter-gatherers lived in communities, agriculture freed people to pursue other livelihoods and to congregate in towns and cities and to be supplied with food from the countryside.

Scholars have debated the origins and spread of agriculture. Jared Diamond's *Guns, Germs, and Steel* argues for five centers where food production arose independently: Southwest Asia (also referred to as the Near East or Fertile Crescent); China; Mesoamerica (central and southern Mexico and areas of Central America); the Andes of South America, and the Eastern United States. There are four other possibilities for the independent agricultural origins: the Sahel of Africa, tropical West Africa, Ethiopia, and New Guinea.^[1]

Wheat had its origins in Mesopotamia in the Tigris and Euphrates river valleys about 10,000 years ago. By about 1000–3000 B.C., Egyptians were already consuming yeast-leavened bread. Corn is considered to have its origin in the Mexican plateau. Native Americans knew corn, squash, and beans as the three sisters. Archeological studies in Hunan province, China suggests that cultivation of rice dates back 6000–7000 years and quickly spread across the East Asian crescent from Assam in Northeast India to Yun-nan, China. Soon it became a dominant cultivar, occupying

the major river valleys and making it the most important cereal grain in Asia. It is a staple food for more than three billion people, with most Asians depending on it for their caloric intake. These—wheat, corn, and rice—are the three basic grain crops that together dominate the agricultural scene of the world.

FLUCTUATIONS IN AGRICULTURAL USES

However, the expansion of cropland and population did not proceed unabated at all times and places. The Black Death of 1348–1349 was followed by repeated, smaller epidemics. During the 15th century, there were fewer people in the European countryside than at any time since about 1150. By the mid-15th century, probably 60% of the plowed cropland in the Parisian basin was no longer planted. Forests reclaimed some land, and pasture replaced some cropland. As a result of less intensive land use, peasants enjoyed more meat and higher quality breads in their diet because of the depopulation of the countryside.^[2] Native Americans succumbed to disease such as smallpox after European contact.^[3] The “Indian old fields” of the Eastern woodlands, the Indian mounds of urban Mississippian settlements, and the abandoned irrigation works of the Southwest attested to Native Americans’ land uses.^[4] Indians repeatedly used fire to renew grasses for grazing animals and left open woodland, where little underbrush hindered travel of the arriving Europeans.^[5]

MAKING LAND MORE PRODUCTIVE

As there is a strong relationship between natural chemical elements in the soil and the ability to feed people,^[6,7] early economists such as Malthus saw population as being limited by the amount of arable land. Through the centuries and especially in the 20th century, humans succeeded in producing more per acre, so that the correlation between the amount of arable land and the food production is no longer as strong as it once was. Various societies learned to rotate crops utilizing legumes. Irrigation and drainage, often on fertile soils, have increased production, as have plant selection and breeding and pest protection. As agricultural chemists began understanding more about plant growth in the 19th and 20th centuries, humans began mining guano and phosphorous for transportation around the world. The most far-reaching development affecting land use for agriculture has been the development of the Haber–Bosch process to synthesize ammonia. By one estimate, these nitrogen compounds provide between 60% and 80% of the nutrients available to the most commonly produced grain crops and are perhaps equal to half of the total nitrogen fixed by all bacteria in natural resource systems.^[8]

LEGACY OF COLONIALISM

The creation of new nations from the former European colonies triggered vast sociopolitical changes that have altered land use. In places where traditional agricultural systems had been sufficient to feed a small population, western medical advances expanded the population.^[9,10] Many new nations could not, or did not, build agricultural supply and production systems, including agricultural chemicals, to grow additional food. With more pressure on production, the result was too often indiscriminate exploitation of land in most developing countries. The considerations of ecosystem integrity and the need to maintain biodiversity are not considered in many developing countries. Large-scale deforestation as in Southeast Asia and South America and expansion of cultivation into wildlife reserves became rampant for several reasons, including increasing population, greater number of people searching for land, and economics. In the richer western countries, the application of soil and water conservation technology and financial support from governments initiated a land use system more dependent on science.^[7] In the centrally controlled economies of the Former Soviet Union and other socialist countries, land use was strictly determined by the state. Although land use was designed according to landscape conditions, pressures to enhance productivity resulted in less care for the land, leading to severe land degradation.

GLOBAL LAND USE PATTERNS

In a modeling study, Ramankutty and Foley demonstrate the extent of natural ecosystems that were converted for agricultural use during the last three centuries.^[11] Fig. 1 is based on the empirical data they generated and shows the changing areas for forest, grassland, and cultivated land in the world and for several regions. The pattern of land use change in Africa (Fig. 1B) mimics the global pattern (Fig. 1A) due to the availability of land for agricultural expansion. Fig. 1C shows the situation of South Asia, a region where limits of available land for agriculture have been met. The remaining forest and Savanna land in this region have many constraints for agricultural use. Fig. 1 shows the case of the former Soviet Union countries where major change in land use has been the conversion of Savanna to agricultural use. The forested land of this region has low temperature as a major constraint for grain production and so less-forested land is converted for agricultural purposes.

Land use is not only the growing of crops or grazing of animals but also the architecture of fields. The layout and distribution of fields came about initially for efficiency of farm practices (access to the fields by the farmers) and later by concepts of soil and water conservation. Field layout had its best design in modern irrigated systems, and these

Fig. 1 Change in land cover area from 1700 to 1990. Graph (A), Global; Graph (B), Africa; Graph (C), South Asia; Graph (D), Former Soviet Union countries.

Fig. 2 (A) Soil Conservation Service demonstration project at Coon Creek, La Crosse County, Wisconsin, U.S.A. 1934. (B) Soil Conservation Service demonstration project at Coon Creek, La Crosse County, Wisconsin, U.S.A., 1967 (of approximately the same area of the 1934 photograph in A).

are evident even in developing countries. However, field size, shape, and patterns show a lack of organization in traditional systems. Many western countries went to great extent to reallocate land to enhance efficiency and economies of farming. In Belgium, e.g., this process took place in the 1960s and was called “ruilverkaveling” or land reallocation. In other countries, economic pressures induced such changes. Fig. 2A and B shows an example of change in field architecture over a 50-year period in the United States.

The beginning of the new millennium is characterized by a number of conditions that affect or even control agricultural sustainability. The world population of six billion people is projected to increase to nine billion in the next few decades, and much of the increase is to take place in the countries that can least afford to enhance the quality of life for population.^[7] Agricultural expansion has taken place at the expense of other kinds of land use (Fig. 1). To obtain an idea of the kinds of soils where conversion of land to agriculture was taking place, the authors combined a global land use/land cover map with the soil map of the world. Table 1 shows the distribution of land use as a function of soils.

About 21% of the global land is cultivated and the dominant soils exploited are the Entisols and Inceptisols (mostly for rice cultivation in Asia); Alfisols, Mollisols, and Ultisols (for upland grain crops); and Oxisols (for plantation crops in the tropics). Some of the semiarid grasslands and shrublands in the developing countries are used for grazing, usually nomadic. About 658,000 km² of land (0.5%) is used for urban purposes. The actual amounts vary between countries, and, as shown in the study of Nizeyimana et al. the better quality lands succumb to urbanization faster. This study has shown that the highly productive soils of the United States have a higher level of urbanization.^[12]

Table 1 Land use and land cover as a function of soils (data in 1000 km²).

Soil orders	Urban	Cultivated land	Grass land	Shrub land	Shrubland–Grassland	Savanna	Forest	Wetland	Barren	Tundra
Alfisols	142	5,708	652	454	24	2,669	3,296	26	97	11

CONCLUSION

There are a number of factors that determine land use patterns in a country. In a global perspective, historical land use reflects sociocultural evolution, the impact of pests, diseases, conflicts between nations, developments in technologies, and the pressures introduced by population increases. The conversion of land for agricultural uses is at an increased pace particularly in developing countries although the reverse trend of restoring the original habitat is taking place in some countries such as the U.S. Developments in geographic information technology with appropriate models are enabling the study of evolution of land use. These developments will provide a better analysis in the forthcoming years.

Land Use: Land Cover

Andrew K. Skidmore

Division of Agriculture, Conservation and Environment, International Institute for Aerospace Survey and Earth Sciences, Enschede, the Netherlands

Abstract

The mapping and monitoring of land cover and land use is mature, as production systems for making maps are now routine and available globally. But users continue to demand more information, of a higher accuracy and precision, and at a cheaper price. Innovative methods for mapping land cover at higher levels of accuracy continually develop. At the same time, techniques are becoming more efficient, thereby decreasing costs per mapped unit. This gain in accuracy and efficiency comes from higher resolution satellite sensors as well as improvements in computer algorithms.

INTRODUCTION

Land use and land cover are components of land; land is defined as:^[1]

- Any delineable area of the earth's terrestrial surface, involving all attributes of the biosphere immediately above or below this surface, including those of the near-surface climate, the soil and terrain forms, the surface hydrology, near-surface layers and associated ground water and geohydrological reserves, the plant and animal populations, the human settlement patterns, and human activity (terracing, water storage or drainage structures, roads, buildings, etc.).

Thus, the main characteristics of land are terrain (e.g., landform, soil, and geomorphology), biotic elements (e.g., fauna and flora), results of past land use, and climate. Numerous definitions of land use exist—in general they refer to management activities related to a tract of land or an ecosystem:^[2]

- A series of operations in land carried out by humans with the intention to obtain products and/or benefits through using land resources.

In contrast, land cover is defined as a 3-D element of land, which occurs on the surface of the land:^[1]

- The vegetation (natural or planted) or man-made constructions (buildings, etc.) that occur on the earth's surface. Water, ice, bare rock, sand, and similar surfaces also count as land cover.

Land cover is identified by direct observation, while land use implies that information is determined through an interview or using similar indirect methods. The input of labour,

or implements used in land use, may not be observable but may impact on the land cover. Thus remote sensing can be used for land-cover mapping but not for land use mapping. However, land use may be determined indirectly from land cover; in other words, land use may be mapped using land cover as the intermediate step.^[3] Examples of land cover include wheat, forest, and water. For wheat, the land use may be “grain production,” “grazing,” or “green fertiliser.” Many people confuse the definitions of land use and land cover.^[4]

MAPPING LAND COVER

Prior to 1945, land resources were surveyed by field sampling, often by examination or measurement along transect lines, with the intervening areas filled in by interpolation. An example of this approach, updated using modern Kriging techniques, is shown in [Fig. 1](#), where a series of soil pits were dug across a hillside, and the soil chemistry for each pit analyzed in the laboratory.^[5]

By using aerial photographs, land managers can map visible features in their entirety, allowing field work to concentrate on dubious points or on quantitative sampling within (already) recognized units or strata. The process of manually extracting information from aerial photographs is usually referred to as “interpretation.”

To interpret aerial photographs, one uses a range of clues under the principle referred to as “convergence of evidence.” For example, using this integrated approach, features such as the drainage pattern, or changes in vegetation, may suggest differences in geology, land form, or soil type. An interpreted photograph for a forested area in Australia is shown in [Fig. 2](#). The line work interpreted on an aerial photograph is transferred to a cartographic base map by the “photogrammetric” process.^[6–9] Further information on the application of aerial photographs to a

Fig. 1 Sample locations and interpolated soil properties for a forested hillside in southeast New South Wales, Australia.

variety of land cover mapping applications can be found in the study by Colwell^[10]

The main problem in using aerial photographs is a high labor requirement. In addition, the assignment of boundaries is subjective, leading to inconsistencies by individuals as well as between interpreters, especially over time. Interpretation may be automated using computers; the cover-type classes are labeled on the basis of the brightness values recorded in many bands at a pixel, and the process is fast and objective. Use of spatial recognition (e.g., of field boundaries) is, however, not made. There are many computer techniques available to derive land cover maps from imagery, and these can be split into two broad strategies, namely, unsupervised and supervised methods.

With unsupervised processing, pixels in an image are assigned to spectral classes without users having foreknowledge of the existence or names of the classes. The unsupervised classification uses clustering algorithms to merge pixels into common spectral groups, and then the analyst names the clusters. In other words, the analyst takes the classified map produced by the unsupervised classifier and then assigns a label to each class.^[11]

Supervised classification is where the analyst identifies cover-type classes in the field or from existing maps and then uses this information to identify the classes on the image. The supervised classification method involves three phases. First, gathering prototype (training) data so that areas can be identified on the image. Second, statistics are generated describing the shape and structure of the training area data in the image feature (multispectral) space. Third, the computer labels each unknown pixel into one of the classes based on the class statistics. One of the most commonly used supervised methods is the maximum likelihood classifier.^[11]

An innovation in the 1970s was to combine imagery with ancillary geographic data creating geographic information systems (GIS), in order to increase the accuracy of land cover maps.^[12–15] The GIS handle geographical data, both in the form of “digital maps” and as “attribute data.” Attributes are, for example, tabular data connected to geometric features such as points (grids), lines, and surfaces on a map.

However, soil maps in particular continued to disappoint land managers, especially where vegetation cover obscured the soil response.^[16] To improve the accuracy of soil maps, expert systems based on known relationships between soil characteristics and landscape features were developed.^[17] An example of an expert system classification is given in Fig. 3, where the relationship between soil and landscape (defined in rule bases by soil scientists) is used to map land cover from landscape data (such as elevation, slope, aspect, solar radiation, parent material, etc.) and remotely sensed imagery. The mapping of land cover with expert systems yields higher accuracy maps compared with more conventional methods, such as a supervised classifier.^[17]

LAND-COVER MONITORING

Changes in land cover may be rapid (e.g., clearing a forest for agriculture) or relatively slow (e.g., tree damage and death due to acid rain). Changes may also be predictable and cyclical (e.g., seasonal variation in tree leaf cover) or unpredictable (e.g., fire damage to vegetation). Using a single aerial photograph or satellite image, an interpreter may identify patterns (either manually or by computer enhancement and classification) indicating that land cover has altered. It is possible to monitor land cover change by mapping an area on two dates and then calculating the difference in land cover with a GIS, using a technique often referred to as “postclassification comparison.”

Various techniques have been developed to compare multirate remotely sensed imagery.^[18] The techniques have been grouped into categories of change detection method by various authors. Postclassification comparison has been described above and involves a comparative analysis of independently classified maps. Other

Fig. 2 An interpreted black and white aerial photograph showing forest-type boundaries on the south coast of New South Wales Australia.

methods include multivariate classification, which is a mathematical combination of two images, as well as simultaneous analysis of multitemporal data.^[19–21] Innovative methods for change detection using wavelets have been suggested.^[22]

All authors agree that accurate geometric registration of imagery is essential for good results. In addition, there is no single optimal method for change detection, as contradictory results have been generated under different (empirical) conditions. However, it is obvious that dramatic differences

Fig. 3 Expert system interface written in IDL. The accuracy of this map, showing coastal wetland vegetation, is 62%.

Fig. 4 Annual average NDVI calculated for Kenya from 1981 to 1990. A red to green color indicates high biomass and high vegetation vigor (e.g., 1990 was a wet year), while yellow indicates drought conditions (e.g., 1984).

occur between images (see Fig. 4), which show the average annual normalized difference vegetation index (NDVI) derived for Kenya from 1981 to 1990. In this series of figures, a red to green color indicates high biomass and high vegetation vigor (e.g., 1990 was a wet year), while yellow indicates drought conditions (e.g., 1984). Such data sets may be processed using the change detection techniques described above.

ACCURACY OF LAND-COVER MAPS

The main products from a GIS, as well as from remotely sensed images, are maps (or a summary of information from maps). Possibly the most important question to be asked by a user is “how accurate is the spatial information?” Quantifying error in maps is based on various statistics derived from the error matrix (also called a contingency table or confusion matrix), which was first expounded for remotely sensed data in the 1970s.^[12,23] The aim of the error matrix is to estimate the mapping accuracy (i.e., the number of correctly mapped points) within an image or map. An error matrix is constructed from points sampled from the map. The reference data collected in the field (also called ground-truth data) are compared with the classified (or image) data.

Two points are particularly relevant to the discussion of accuracy. First, should we map class boundaries (e.g., Fig. 2) or should continuous surfaces (e.g., Fig. 1) be used to represent a landscape? The standard method of calculating error matrices relies on class boundaries. However, as most landscapes are actually continuums, and as it is impossible to map the subtlety inherent in a continuous surface using classes, new methods for assessing the accuracy of a continuous surface are required. Second, when attempting to verify maps, a mapped area becomes a historical record. A land cover map classified using an old image is impossible to check (e.g., a farmer may plant different crops each year). A complete description of accuracy assessment procedures and issues is given by Skidmore.^[24]

LAND USE DATABASES

As noted above, land cover may be derived from remotely sensed data and aerial photographs. It was remarked earlier that land cover and land use are frequently misunderstood and confused. A land use system is defined as:^[3]

- A specific land use, practised during a known period on a known and contiguous area of land with reasonably uniform land characteristics.

The importance of the land use concept is that “use” is often not detectable on an image, e.g., consider the land use “applying fertilizer.” The impact of this use operation on land cover may not be observable (e.g., due to a short time period between application and observation, or the spatial resolution of the remote-sensor system being too coarse). Thus, information on land use requires an interview with the person who controls or carries out the land use. Note that land use may often be correlated with impacts on actual land cover, allowing land use to be mapped by using land cover as an intermediate step.

Land use data collected by numerous agricultural and regional development projects are generally not poor accessible. These data are hidden away in survey reports, and when available, may be difficult to use due to non-standard descriptors. A database has been developed^[3] to consistently record land use data (see <http://www.itc.nl/ha2/ace/>).

CONCLUSION

The mapping and monitoring of land cover and land use is mature, as production systems for making maps are now routine and available globally.^[25] But users continue to demand more information, of a higher accuracy and precision, and at a cheaper price. Innovative methods for mapping land cover at higher levels of accuracy continually develop. At the same time, techniques are becoming more efficient, thereby decreasing costs per mapped unit. This gain in accuracy and efficiency comes from higher resolution satellite sensors as well as improvements in computer algorithms. The trend is clear; more sophisticated land cover products at lower prices and available all over earth.

Abstract

Geographic information system (GIS) and related technologies (e.g., remote sensing and global position system) have proven to be a valuable tool in land use planning activities. The GIS approach is important in this area because it provides functions to capture, store, organize, and analyze spatially referenced data. Moreover, GIS has been coupled to a variety of models (e.g., crop productivity, hydrology, and water quality simulations) and may be an important component of spatial decision support systems and land resource information systems. GIS enhances model flexibility and efficiency in these systems where it is often regarded as a centralized data analysis, management, and planning system. As a result, decision-makers and land use planners in private companies, in universities, and at various levels of the government are using GIS to develop spatial environmental databases, perform land evaluations, and analyze and manage resources. There is no doubt that the use of GIS and GIS-based systems in land use planning activities will continue to increase in the future, as more detailed digital environmental data sets become available and the capability of computers to handle large volumes of data increases.

INTRODUCTION

Agricultural scientists are required to provide information needed to address land degradation and land use conflicts confronting the world. As the population increases and land becomes a commodity in many parts of the world, careful planning of the use of land must be undertaken to accommodate conflicting people's needs and preserve and/or protect the environment. The decision about the use of land must be made based on analyses of each potential use in terms of its economic and biophysical suitability to the specific tract of land and possible impact to environmental degradation.

GEOGRAPHIC INFORMATION SYSTEM (GIS) USE IN LAND USE PLANNING ACTIVITIES

The goal of land use planning is to make decisions about the use of land and resources.^[1] Its implementation is often driven by future people's needs in terms of productivity and environmental sustainability. Land use planning is important in highly populated communities primarily due to conflicts between competing uses and interests of users.^[2] In this case, planning activities are tailored to make the optimal use of the limited land resources. In general, the land use planning involves sequentially an organization of

thoughts and establishment of long-term goals, a land evaluation that includes appraising alternatives and finally designing and implementing the plan. Land evaluation is the most important aspect of this process.

The information within a GIS consists of a spatial component represented by points (e.g., well locations), lines (e.g., streams and road networks), or polygons (e.g., soil delineations) and attribute data or information that describes the characteristics of spatial features. The spatial entity is referenced to a geographic coordinate system and is stored in either a vector or a raster format.^[3] GIS is primarily used in the development of spatial databases and land evaluation, a procedure in the land use planning process that is aimed at determining the suitability of land units to existing and alternative uses and the potential impact of each on the environment.

Development of Spatial Databases

GIS stores, retrieves, and allows the efficient manipulation of database information. It provides powerful analysis and relational database facilities to modify and/or integrate spatial data from different sources and resolutions as well as advanced visualization functions to display output data in the form of interpretative maps. In this case, land attributes and qualities are derived from geographic databases and used to determine land suitability, limitations, or ratings for

various land use types. The analysis results may be presented in tabular or graphical form and are intended to provide key information necessary for land users or planners to make meaningful decisions about land management and conservation and/or land use planning.

Site Suitability Analyses

A site suitability analysis typically involves the assessment of the level of affinity a specific land has for a particular use. Soil information available in soil databases is rarely enough for site evaluations. In addition to soils, the analysis often integrates local information on landforms, land uses, the relative location of the land, and associated social and political restrictions. The proposed use may have additional limitations that should be taken into account; e.g., an analysis for suitable sites for the land application of sewage sludge should consider the physical, chemical, and biological properties of the waste in soil and water.^[4,5]

GIS is efficient in identifying and ranking sites for various land use planning activities. First, site-specific analyses often require many and detailed data sources. Second, GIS overlay features, logical operations, and display functions are tailored to speed up data processing and therefore allow efficiently suitability class assignment and graphical display of results. A good example is the use of GIS for locating appropriate sites for the forestland application of sewage waste.^[6] The authors derived physical site suitability ratings for an area in Vermont based on U.S. Environmental Protection Agency guidelines^[7] and merged them with social and political restrictions of the state and counties to derive a land applicability classification. Similar GIS-based approaches have been used to locate sites for solid waste disposals.^[8]

Linking GIS and Models

The spatial databases and associated attribute data described above may be part of a GIS/model graphical user interface (GUI). These models may be those that determine land suitabilities or those that simulate water quality for environmental impact assessments. As an entity of GIS/model GUI, GIS allows easy access to database attributes by various algorithms, statistical software, and environmental models for a variety of land use analyses. In addition to model parameterization, a full integration of GIS and models also allows the user to interact with various modules, select data input and module utilities, and display the graphical and/or tabular representations of modeling results.^[9] The use of this type of interface reduces significantly the processing time and resources required to develop input data and run the model. GIS/model linkage has been accomplished for field- and watershed-scale hydrology/water quality models such as the Leaching Estimation and Chemistry Model^[10] and Agricultural Non-Point Source Pollution^[11] model. Results of these analyses are used to support management and land use planning activities in the farm or watershed.

The GIS/model GUI may also be part of a spatial decision support system (SDSS). In addition to modeling parameterization, SDSSs offer the users with functions to evaluate different land use scenarios necessary for making management recommendations and/or land use planning decisions. Results may be used by farmers to adjust the management practices of distinct fields in a given farm or may be used by field officers to help farmers set priorities while providing technical assistance for nutrient management planning. Fig. 1 shows a flow diagram indicating data

Fig. 1 The integration of GIS, spatial database, and models.

integration in a GIS with models for water quality assessment in watersheds.

GIS has been incorporated in many land evaluation systems, so that planners and public officials can take advantage of its spatial modeling and visualization capabilities. An example of such a system is the U.S. Department of Agriculture–Natural Resources Conservation Service's Land Evaluation and Site Assessment (LESA).^[12] The land evaluation portion of LESA determines soil productivity levels, farm size, and agricultural sales volume; the site assessment portion deals with factors such as location, amount of non-agricultural land, and zoning restrictions.^[13]

GIS, in GIS-based LESA systems, is used in both modules and at all levels of the analysis.

Development of Land Resource Information Systems (LRISs)

A number of land information delivery systems have been developed to make spatial data available to users for application in various aspects of land use planning. These systems, also called LRIS, are multipurpose systems that integrate geographic databases and GIS tools to analyze, record, report, and display spatial data relationships. Some of these systems have been embedded into the World Wide Web for quick and easy access and analysis via Internet browsers.

RELIABILITY OF GIS-BASED ANALYSIS RESULTS

GIS and GIS-based systems used in spatial data analyses for land use planning have grown lately. GIS is particularly attractive in these areas because it allows overlay of spatial data sets and the merging and analysis of attribute data from different sources. The resulting data are obtained using data from digital and paper maps of different scales or acquired at different resolutions such as in the case of digital elevation models and remote sensing imagery. The combination of such data layers may produce unrealistic data and consequently lead to erroneous predictions. The question is, how reliable are these results when used for developing land use and management plans? A discussion on the propagation of error and uncertainty in GIS-based systems is provided elsewhere.^[14]

The accuracy of GIS-based land evaluations is a function of the quality of attribute data and mapping delineations of databases, and the type of model or assessment scheme used in the analyses. Various algorithms for assessing the quality of GIS analysis results as affected by error and uncertainty in GIS layers and their propagation are part of popular GIS and image analysis software (e.g., Arc/Info and ERDAS Imagine). The results, which are often in the form of reliability diagrams, are not used by average GIS

practitioners. This is probably due to the fact that they are not easy to understand or interpret. Similarly, models vary depending on how each represents various processes of the system. Lumped parameter models and indexing/ranking schemes are mostly used in land evaluations because they are easy to parameterize. However, these models ignore spatial variations of parameters throughout the field, watershed, or region of study. Furthermore, models originally designed for fields and watersheds are often applied to regional analyses, thus adding some level of uncertainty in modeling predictions; e.g., most land use planning programs use conventional methods of land evaluation. Each land parameter is given a range of values with corresponding ratings showing its suitability to crop production. These indexes are added or multiplied to create a single index that is to rank land units. The method is simple but carries a high uncertainty because breaks between two ranges or ranks are subjective.

The effect of map scale and resolution on environmental assessment and modeling output data has been subject to many studies. Raster-based GIS systems require that a grid cell size be defined prior to the analysis. However, as pixel size increases above the resolution of the original data, the spatial variability decreases. This causes a decrease in the predictive power of generated input parameters particularly for small land areas.

CONCLUSION

GIS has been used primarily in land evaluation, a procedure in the land use planning process that deals with determining land suitability to existing and alternative uses and the potential impact of each use on the environment. GIS and GIS-based systems are often considered to as integrated spatial information systems for data analysis needed in land use management and planning activities. Despite the advantages of GIS outlined above, the land use planner should be aware of the error and uncertainty in GIS and GIS-based analyses, resulting from digitizing and scaling inaccuracies, data conversion between vector and raster formats, and others. Finally, GIS implementation in land use planning activities can be expensive. In addition to costs associated with hardware and software purchase and maintenance, a high level of technical expertise is required to perform complex modeling tasks in land evaluations for alternative uses and to sustain databases. Nonetheless, the demand for GIS and GIS-based analysis systems in land use planning is to increase in the future as more detailed spatial data sets become available.

Landfill Sites: Revegetation

Institute for Natural Resources and Land Management, Hong Kong Baptist University, Hong Kong, China

Abstract

The disposal of waste to land has been the prime means of waste disposal since the evolution of humans. In the past, people disposed of refuse at dumping points within a reasonable distance, e.g., outside the city wall. As cities expanded, dumping points expanded and wastes were piled up until they reached an unacceptable level and were eventually covered by soil. These rudimentary open dumping methods are common in small and remote villages. Landfill was developed from open dumping and is a method of codisposal of municipal solid waste and soil, on land with proper engineering consideration. Alternative names are sanitary landfill or controlled tipping; however, it has become more common simply to call it “landfill.” It can be regarded as the only way for the ultimate disposal of municipal solid waste in a controlled manner that causes minimal nuisance to public health or safety. Hazardous or radioactive wastes are generally not accepted in ordinary landfill sites.

LANDFILL DESIGN AND OPERATION

The daily operation of a landfill site is to spread and compact the waste unloaded from vehicles by using waste-moving equipment. A better practice is to cover the waste with another layer of waste or with a temporary cover soil of about 0.2 m thick and compact with compactors to maximize the landfill capacity. The layers of waste and soil formed are called landfill cells. The final top cover is a layer of soil about 0.2 to 1 m in depth. To prevent differential settlement, a high degree of compaction over the whole area of the cell is maintained. An *in situ* density of 1.2 t m^{-3} can be achieved using a bulldozer.^[1] Where densities of only $0.6\text{--}0.7 \text{ t m}^{-3}$ are achieved, settlement of 20% or greater is expected; while on sites where a high density of $1.0\text{--}1.2 \text{ t m}^{-3}$ is achieved, the settlement may be 10% or less.^[2] A site is considered completed after its filling capacity is reached. Completed sites have to be redeveloped, and special techniques have to be applied for vegetation establishment.

There are two contrasting approaches to landfill design: 1) to consider landfill as a bioreactor and try to maximize waste degradation; and 2) to attempt to isolate the embedded waste from the outside environment as far as technology can achieve and costs allow. The former principle relies upon attenuation of the leachate both within the waste and in the adjacent geology by biological and physicochemical processes. However, the contamination of adjacent environments and groundwater has been experienced.^[3]

The latter is also called containment landfill, where the rate of release of leachate into the environment is extremely low and landfill gas is either flared on-site or collected for energy recovery.^[4] In modern landfill design, the latter concept is commonly adopted to protect nearby environments and minimize pollutant discharge.^[5] To achieve this, an impermeable bottom liner is laid at the base of the site to avoid seepage of leachate into groundwater or adjacent water bodies. The very top of the landfill cells is covered by a thicker layer of inert soil, usually about 1–1.5 m thick, which is compacted by machinery.^[1] In order to further restrict gas migration, a costly synthetic impermeable layer may be laid together with the soil, but the efficiency of the composite liner (also called landfill cap) depends on the material used.^[6] Between the bottom liner and the landfill cap is a network of pipes to collect leachate and gas. The top liner not only prevents gas migration into the topsoil, but also prevents the infiltration of rainwater into the landfill.

Other criteria to be considered in the design, planning, and development of a landfill include engineering aspects, mode of landscaping, environmental impact, operational issues, and legal questions.^[1,2,7]

ANAEROBIC DEGRADATION OF MUNICIPAL SOLID WASTE

Anaerobic biodegradation of waste embedded in landfill cells generates landfill gas. The typical composition of pure

landfill gas is about 60% carbon dioxide (CO_2) and 30% methane (CH_4 ; v v^{-1}); however, concentrations as high as 89.3% CO_2 and 77.1% CH_4 have been detected.^[1] In addition to the major gases present in landfill cover soil, other organics, such as alkanes, aromatic compounds, cycloalkanes, terpenes, alcohols, ketones, and phosphine, and over 140 volatile organic compounds that are generally at levels of $<0.1 \text{ mg m}^{-3}$ have been identified in landfill gas.^[8,9] The production of gases depends on climatic factors and the chemical nature of the waste.

The aqueous secondary waste percolating through embedded municipal solid waste and its degradation by-products is called landfill leachate. In most cases, rainwater contributes the greater portion of water that forms the leachate. Groundwater and other water sources from the adjacent environment may also supply moisture to the waste and produce leachate. Biodegradation of waste also produces water. The properties of leachate depend mainly on the nature of the embedded waste and the design of the site, which determines the infiltration rate of rainwater. High ammonium–nitrogen ($\text{NH}_4^+\text{-N}$) is a general characteristic of landfill leachate, as $\text{NH}_4^+\text{-N}$ oxidation generally requires aerobic conditions. It is not uncommon for leachate to contain in excess of $1000 \text{ mg NH}_4^+\text{-N l}^{-1}$.^[10] The ratio of biochemical oxygen (O_2) demand to chemical O_2 demand of leachate collected from a new site is generally higher than that of leachate from an old site.^[11]

LANDFILL FACTORS AFFECTING PLANT GROWTH

Although the design and operation of landfills in different countries are not the same, the basic problems of landfill gas and leachate contamination are common to all.^[12]

Landfill Gas

Flower, Gilman, and Leone^[13] presented one of the early reports on how landfill gas affects tree growth and how its injurious effects may be prevented. Gas problems were experienced in sites where the clay layer was not formed properly or was cracked by uneven settlement of topsoil. Similarly, for landfill sites without an impermeable top liner, or for areas in larger sites where only temporary cover was laid, high CH_4 and CO_2 and low O_2 were detected in the cover soil and tree growth was affected.^[14] The tolerance of 10 subtropical woody plants to landfill gas was compared,^[15] and the results indicated that legumes were generally more resistant to landfill gas. For sensitive plants, such as *Liquidambar formosana* and *Castanopsis fissa* (both nonlegumes), chlorosis and stunted growth were observed after they had been fumigated with simulated landfill gas. Adverse effects of landfill gas on plants were caused by high levels of CO_2 ($>20\%$) in the rhizosphere,

Fig. 1 Stratification of landfill gas in cover soil. Light penetration and occasional drying make zone A unsuitable for root growth. In zone B, root growth is stimulated by low levels of CO_2 (e.g., $<10\%$). Zone C is restricted for root growth by high levels of CO_2 (e.g., $>10\%$). Plants with roots sensitive to CO_2 (e.g., $>10\%$) have a shallow root system in zone B. Plants with moderate sensitivity to CO_2 have an intermediate depth of zone B for root growth. Plants tolerant to high CO_2 level have a deep root system.

rather than by low partial pressure of O_2 ($<10\%$). However, low levels of CO_2 ($<10\%$) fumigation in the rhizosphere stimulated root growth, as low levels of gaseous CO_2 or bicarbonate stimulate cellular respiration in root cells. Therefore, the stratification of CO_2 in landfill cover soil stimulates shallow root system development (Fig. 1). A landfill gas fumigation test indicated that differences in sensitivity of plants to gas level also caused differential stimulatory (*Lotus corniculatus* and *Trifolium pratense*) and inhibitory effects (*Vicia villosa* and *Trifolium repens*) on root growth subjected to landfill gas (CO_2).^[16] However, the mechanisms by which CO_2 , especially at high concentrations (e.g., $>10\%$), differentially affects tissue respiration are not fully understood.

When the O_2 partial pressure is low, leguminous nitrogen gas (N_2) fixation declines. Under a subambient partial pressure of O_2 , N_2 fixation by a nodule is proportional to the O_2 concentration.^[17] The influence of CO_2 after landfill gas contamination on the growth and activity of N fixing nodules is complicated. CO_2 at high levels as may exist in landfill cover soil was shown to be effective in inhibiting rhizobia-legume N_2 fixation, and the effect was reversible within 1 hour.^[18] However, it has been observed that rhizobia are effective in nodulating woody legumes (*Acacia confusa* and *Leucaena leucocephala*) under landfill gas fumigation conditions and are effective in N fixation.^[19]

CH_4 , a major ingredient of landfill gas, is physiologically inert to plants. However, in the presence of CH_4 , O_2 in the rhizosphere is depleted. CH_4 in cover soil can be converted to CO_2 by methanogenic bacteria.^[20] This process decreases the level of CH_4 and increases the level of CO_2 in cover soil.

Landfill Leachate

The problem of leachate seepage normally happens in confined areas and usually at the edge of a site. "Leachate breakout" is caused by high leachate levels within the waste and ingress into a site through weaknesses in the cap or on an uncapped site.^[21] The breakout can cause injury to trees due to leachate toxicity. In West Virginia, the United State, six tree species were irrigated with leachate for 4 years resulting in significant mortality.^[22] In Hong Kong, *A. confusa* irrigated with leachate exhibited growth depression to about 25% of the control after 50 days.^[23] The phytotoxicity of treated and untreated leachate samples collected from three landfills in Germany was evaluated using luminescent bacteria and bioassays conducted using the aquatic plant *Lemna minor* and terrestrial plants *Brassica rapa* and *Lepidium sativum*.^[24] In addition to high levels of $\text{NH}_4^+\text{-N}$, the accumulation of chloride and increases in soil salinity are major causes of phytotoxicity of leachate.^[25] On the contrary, when leachate concentration and irrigation rate were properly controlled, leachate irrigation could benefit plant growth.^[26,27]

Leachate recirculation on landfill sites can be regarded as an alternative approach to leachate treatment.^[28] It was found that leachate recycling increased the rate of biodegradation of organics and the landfill would become "stabilized."^[29] When leachate recycling was practiced, the duration of CH_4 production could be shortened from 20–30 years to a few years.^[30] Application of leachate to the surface of a landfill can result in a significant decrease in leachate volume due to evapotranspiration. However, leachate recycling is not commonly adopted in cities demanding groundwater for their main water supply and for landfill without proper bottom liners. For example, leachate recycling has been banned in New Jersey^[30] and is also not allowed by law in the United Kingdom.

Other Landfill Factors

In addition to gas and leachate, a number of unique characteristics found in landfill final cover soil might affect plant growth. For landfill sites with a high-quality composite cap, leachate contamination of cover soil is unlikely. The physical and chemical properties of the cover soil being laid on top of the impermeable cap are therefore crucial for the performance of the vegetation established there. Nutrient deficiency, especially N, is a common characteristic of low-quality cover soil, such as demolition waste or unweathered soil.^[31] Application of fertilizer is therefore necessary.

Waterlogging is common in landfill sites where the evaporation rates are low or the rainfall is intense.^[21] On the contrary, the problem of drought was reported in subtropical landfill sites.^[32] Drought problems may be severe in landfills located in places with a high evaporation rate. The impermeable top liner imposes a constraint

on plant growth because of the relatively shallow effective root zone for water storage.

Another common feature is the high bulk density in cover soil caused by the compaction of soil and waste. Excessive compaction of soil might hinder the penetration of common plant roots. The restriction of root growth depends not only on bulk density but also on soil particle size. Plant roots will rarely penetrate into light textured soils with a bulk density greater than $1.7\text{--}1.8\text{ g cm}^{-3}$ or heavy textured soils with a bulk density greater than $1.5\text{--}1.6\text{ g cm}^{-3}$. It was demonstrated that the growth of Austrian pine roots on a silt loam and sandy loam was restricted at bulk density of $1.4\text{--}1.8\text{ g cm}^{-3}$.^[33] A study conducted in Hamburg, Germany, indicated that the reduction of compaction during construction of landfill cover soil or the use of amelioration increased the water retention capacity in the topsoil layer.^[34]

Elevated temperature in cover soil, e.g., 45°C ,^[15] caused by the heat release process of the biodegradation of waste and solar radiation on bare lands, is another common feature of landfill sites. The adverse effects of elevated temperature in landfill cover soil on plant growth have been summarized.^[21]

Landfill cover soil may have elevated metal levels after contamination by leachate that has high metal levels. However, landfill cover soil does not normally accumulate metals to such high levels that it has harmful effects on vegetation. On old landfill sites, other landfill factors such as landfill gas are more significant than metals in their affect vegetation performance.^[35]

There is a lack of information related to the role of mycorrhizal fungi on tree growth on closed landfills. The need for mycorrhizal tree seedlings in site restoration programs has been questioned.^[36,37]

Suitable Tree Species for Landscaping Completed Landfill

There are two basic criteria that determine the suitability and success of a plant to be established on a landfill site: tolerance to landfill gas and/or leachate and drought tolerance. The superior performance of *A. confusa*, *Acacia mangium*, and *Acacia auriculiformis* is mainly due to their high drought tolerance^[38] and capability to fix N when growing on N-deficient soil.^[15,39] Due to their high drought tolerance, *Tristania conferta*, *Eucalyptus citriodora*, and *Eucalyptus torelliana* are some of the non-legumes that also show superior performance in landfill.^[31] Tree species suitable for woodland establishment in subtropical completed landfill are listed in the studies by, Chan, Wong, and Whitton,^[19] Chan and Wong,^[31] and Chan, Wong, and Whitton,^[40] in which about one half of the trees are legumes. Suitable and unsuitable trees for planting in the United Kingdom are listed in the study by Dobson and Moffat,^[21] of which five of the 30 "likely to be tolerant" trees are legumes.

ECOLOGICAL RESTORATION AND END LAND USE

The number and size of landfill developments are increasing in most cities. As a direct consequence, more completed landfill will be sites awaiting redevelopment in the near future. Due to uneven settlement of the top profile and the potential accumulation of explosive landfill gas in infrastructure, building estates or large civil constructions is not recommended on completed landfill sites. Therefore, closed landfill sites are commonly converted into parks, golf courses, or botanical gardens.

A sustainable landfill should be properly managed so that the environmental risk is acceptable.^[41] However, information about sustainable development of closed landfill is limited. To protect the environment, an assessment of the impact of landfill on ecosystems is required throughout the operation and postoperation stages of a site, both within the site boundaries and in the vicinity of the site.^[2]

The interaction between landfill factors and organisms inhabiting landfill sites is complex. In the rhizosphere, vegetated landfill caps may enhance CH₄ oxidation, but the effects seem not to be significant or consistent.^[42] Introduction of earthworms to cover soil on landfills in the United Kingdom was successful, but the physical soil conditions of the cover soil have not changed significantly after 3 years.^[43] *In situ* flaring of landfill gas may produce oxide deposits containing rather high concentrations of elements that form volatile species such as phosphorus, arsenic, antimony, and tin.^[44] However, adverse effects of such deposits on ecosystems established within landfill sites have not been reported.

On the contrary, all landfill sites are not necessarily unsuitable for ecosystem development. An ecological study was conducted on temporary cover soil in two landfill sites in Hong Kong, on which the cover soils were slightly contaminated by landfill gas and leachate. Higher plant coverage and diversity and higher densities of soil and litter animals were detected on these two sites, compared with normal sites. This was due to the seepage into landfill cover soil of leachate elevated in nutrient levels, especially N, which benefited plant growth. Indirectly, the presence of plant coverage and leaf litter benefited soil and litter fauna in the sites.^[45] The absence of plant cover at a completed landfill site limited the occurrence of some common soil animals such as Diplopoda, Hemiptera, Isopoda, and Isoptera.^[46]

A 4-year revegetation study was conducted on one of the world's largest landfills in Hong Kong, constructed with composite impermeable top liners, and no landfill gas and leachate problems were detected. The performance of 24 tree species was tested and the results indicated that *A. confusa*, *A. mangium*, *A. auriculiformis* (legumes), *E. citriodora*, and *E. torelliana* (nonlegumes) served as excellent pioneer species, while other species, such as *Castanopsis fissa*, *Cinnamomum camphora*, and *Machilus thunbergii* (native species to Hong Kong) had extremely

high mortalities on the test site. After 3 years, the pioneer species provided shelter for native species. Animals, including insects and small vertebrates, started to inhabit the newly established woodland, with a species richness comparable to nearby natural landscapes.^[31] Tree planting has not been recommended in closed landfill sites in the United Kingdom as trees were suspected to damage the landfill top liner. However, evidence indicates that tree roots will not penetrate the top liner if it has a high bulk density of about 1.8 g cm⁻³.^[14,47] The roles of trees in ecologically sound and sustainable reclamation of old landfill sites have been reviewed.^[35]

Wildlife colonization may also take place in woodlands established on landfill sites. The succession and maturation processes and the sustainability of the woodland rely on the physical and chemical properties of the man-made cover soil and also on climatic factors. Sustainable development of an ecosystem with vegetation comparable to ecosystems in the adjacent natural or less disturbed lands has proved to be feasible on closed landfills. However, special technologies, management skill, and understanding of landfill design and operation are generally required.

Landscape

George Hall

School of Natural Resources, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Landscape is the portion of land that can be seen from a single vantage point. The shape of the land has an effect on soil conditions. This entry reviews the categorization of the parts of the landscape and their impact on land use and management.

INTRODUCTION

The landscape is defined in several different ways. It has been defined as the portion of the land surface that the eye can comprehend in a single view.^[1] The glossary of soil science terms^[2] states that the landscape is a collection of related landforms; usually the land surface which the eye can comprehend in a single view. Landforms are any physical, recognizable form or feature on the earth's surface.^[2] Thus, the scope of the landscape is variable depending on the position of the observer, whether in a deep valley or on an airplane flying over the valley. The landforms are the features that make up that landscape.

LANDSCAPE TERMINOLOGY

The terminology used by soil scientists is based on the historic concepts of William Morris Davis and Walther Penck. Wood^[3] and King^[4] formulated models for the fully developed hillslope which included the elements of waxing slope, free face, debris slope, and pediment (Fig. 1). Ruhe^[5,6] developed a soil-geomorphic model in which the soil properties were integrated with the hillslope models. Ruhe^[6,7] modified the Wood and King models by proposing the hillslope elements of summit, shoulder, backslope, footslope, and toeslope (Fig. 1). Following the introduction of the hillslope positions, Ruhe and coworkers^[7,8] formalized terms for geomorphic slope components: headslope for the concave position, sideslope for the linear position, and noseslope for the convex position (Fig. 2).

A different approach was taken by Conacher and Dalrymple.^[9] They used the catena concept and defined the slopes as a 3-D unit extending from summit to the valley floor. The model consisted of nine units, all of which need not occur on a given landscape. Of particular importance in the model were the interactions among soil materials and mobilization, translocation, and redeposition of the material by water and gravity.

LANDSCAPE UNITS

The specific landscape position elements have differing processes and as a result have differing properties. Although these five positions are separately defined, as is the case with many natural phenomenon, the positions and thus the processes grade from one to the other. The following discussion is most applicable for humid climates.

Summit

Where the summit is greater than approximately 30 m in width, much of the water is retained on the surface. This position is considered the most stable, and the water movement is predominantly vertical except near the transition to the shoulder position or on small undulations on the summit.

Shoulder

Convexity is the rule for the shoulder positions. Surface runoff of water is maximized in this element resulting in a highly erosional and relatively unstable land surface. Lateral movement of surface material (soil creep) may become an important process on this part of the landscape. Lateral subsurface water movement or throughflow is often an important process in this landscape position.

Backslope

General linearity is characteristic of the backslope position. The dominant process on this position is the transport of material as well as water. Surface transport of material may be in the form of surface wash, creep, flow, or slump. Lateral subsurface water movement (throughflow) is important in this element. The position is considered to be relatively unstable depending on the degree of slope.

Landscape

Fig. 1 Elements of a hillslope model.

Source: From Ruhe.^[6]

Footslope

Concavity is characteristic of this landscape position. This concavity results in deposition from upslope of particulate material as well as material carried in solution. Seepage zones may be present, and water retention is high. Soils in footslope positions may be heterogeneous due to mass movement, irregular seepage, and non-uniform deposition. Paleosols often can be identified in these positions.

Toeslope

The toeslope element is unstable as a result of its dominantly constructional nature. Materials in this position are

derived from up valley and to some extent from superjacent footslope and backslope positions.

CATENA

The catena concept was proposed by Milne^[10,11] as an interlocking of elements of the landscape. The term is derived from the latin word for chain. In United States, catena is used almost interchangeably with toposequence. Toposequence or local relief carries with it a morphological connotation that is related to a relative elevation and thus to changes in hydrology. Catena on the other hand carries with it a process-response connotation. The soils of a catena differ not only in morphology but also are considered to differ as a result of erosion, transport, and deposition of surficial material as well as leaching, translocation, and deposition of chemical and particulate constituents in the soil. The concept of catena has been used extensively to study the soil genesis.^[12-14]

The morphology and processes of each member of the catena are related to every other member of the catena. It is a dynamic process where in the members of the catena are continuously adjusting to the environmental changes of a given landscape.^[15]

LANDSCAPE MORPHOLOGY

Landforms are individually transformed by erosion and deposition during the process of landscape evolution. Water

Fig. 2 Geomorphic slope components and hillslope profile from an incised valley.

Source: From Ruhe.^[8]

movement is a major driving force that shapes and modifies the morphology of the landscape. To properly evaluate the processes occurring on the landscape, the morphology of the landscape must be determined. This evaluation should include at a minimum: gradient, aspect, and vertical and horizontal curvature.

Water movement on the slopes is largely determined by the planar curvature of the slopes; both the longitudinal and latitudinal profile. Huggett^[13] added surface flow lines to the basic slope shapes (Fig. 3).

Pennock et al.^[16] studied the complexity of water movement on various hillslope elements and curvatures. They used the terms convergent and divergent to identify the slope positions in which water accumulates or disperses. One combination of convergent and divergent slope positions is shown in Fig. 4. In this example, the landscape element with the least moisture would be the divergent shoulder and the element with the most moisture would be the convergent footslope. Other elements would be expected to have intermediate moisture contents.

Landscape models have shown that landscapes are predictable; they have a large non-random variability component. The landscape must be defined in three dimensions, considering the surface configuration as well as the vertical changes in stratigraphic materials.

SLOPE ORIENTATION/ASPECT

Landscape modifying processes are influenced by the slope orientation or aspect. The orientation affects the amount of

Fig. 4 Water movement in a hillslope system.

Source: From Pennock, Zebarth, et al.^[16]

radiation reaching the soils surface which in turn influences the microclimate, and thus, the moisture and vegetation on slopes. In the areas of low relief, aspect has little influence while in the areas of high relief the influence becomes more important.

Global latitude is also a determinant because the angle of solar radiation increases with increased latitude. Thus, shading increases with increased latitude. Aspect becomes most important in the high relief areas between 40° and 60° latitude.^[17] In the northern hemisphere, south-facing slopes receive more radiation and are thus warmer and dryer than north-facing slopes.^[14] The differences in moisture and temperature are reflected in the vegetative and soil process differences for different slope orientations.

IMPLICATIONS FOR LAND USE AND MANAGEMENT

Landscape and Land Use

Most land use decisions are influenced by the landscape characteristics. In agriculture, cropping patterns and cultivation practices are conditioned by the gradient and configuration of the landscape. Conservation practices must be invoked as slope gradients increase. These practices include contour strip cropping and conservation tillage to control erosion. Increasing slope gradients also limit the use of agricultural equipment and increases the cost of production. In steeper portions of the landscape, the land must be utilized for grazing or forestry. Footslope and toeslope positions are more subject to seepage and flooding and thus

may restrict the cropping options on these portions of the landscape.

In urban land use planning, consideration must also be given to landscape. As in the case of agriculture, footslope and toeslope positions are subject to water seepage and flooding, and urban development of these areas must take these limitations into consideration when land use decisions are made. Although housing developments on steep gradients are aesthetically pleasing, they are more expensive to build and maintain and may be subject to slippage and slope failure.

Risks of Soil Erosion

Water, wind, and gravity are each considered agents of soil erosion. Erosion resulting from water and gravity is most commonly related to landscape positions. Wind erosion is more closely related to vegetative soil cover but may be modified by landscape conditions. Soil loss increases as the length of the slope increases up to some maximum. Soil loss increases exponentially as the slope gradient increases. Erosion as the result of gravity (mass wasting) is most common on very steep gradient slopes but may also be found on lesser slopes where the surface and subsurface conditions such as a seep may cause slumps and slips to occur.

On-Farm and *In situ* Water Management

Water management is important in the control of erosion and to provide optimum moisture for plant growth. Diversions and waterways are often used to control water movement on the landscape. On steeper gradient slopes, contour and strip cropping may be used to slow water movement over the soil and thus encourage greater moisture infiltration and retention. Tile drainage may be used to intercept drainage from seeps in the footslope positions. In level or depressional areas where soil water accumulates at or near the surface, tile drainage must be installed to remove the excess water.

Landscape: Classification

Philip Schoeneberger

*U.S. Department of Agriculture—Natural Resources Conservation Service
(USDA-NRCS), Lincoln, Nebraska, U.S.A.*

Abstract

The earth's surface is not uniform, but it can be understood and consistently described. It is a universal human activity to evaluate and categorize the earth's surface into groupings useful for management decisions. The most robust and versatile classification schemes include attributes that capture the surficial form, internal composition, spatial arrangement and distribution, with attention to how these parameters affect vegetation and land management options. Geomorphology provides a framework that integrates these parameters to describe the inherent architecture upon which natural systems and processes operate.

INTRODUCTION

Groups of spatially associated landforms that share common forms, patterns, composition, or site history are called landscapes. Landscapes are a general and convenient way to summarize the context or setting of a land area. Identifying various landscapes and placing them into an orderly array constitute landscape classification. Project purpose and scale (minimum polygon size) determine the most appropriate approach to landscape classification.

Landscapes

The word *landscape* is widely used in at least three different ways, all of which are legitimate and can be readily found in soil-related literature:

1. *Informal context:* Landscape—a portion of land that the eye can comprehend in a single view.^[1] This “everyday” context refers to whatever portion of the earth's surface that surrounds you or whatever you can see outside your window (Fig. 1). It is utterly dependent upon where you happen to be standing. There is a huge difference between “what the eye can comprehend” (see) from a mountain top vs. the view from a coastal plain marsh. This perspective depends exclusively upon your field of view. It encompasses everything, and yet only, what you happen to see (doesn't address things out-of-view).
2. *Explicit Geomorphic context—e.g., mountains (any mountains) vs. plains (any plains):* “Landscape—a broad or unique land area comprised of an assemblage or collection of natural landforms that define a general geomorphic form or setting (e.g., mountain range, lake plain, river valley, etc.). Landforms within a landscape share spatially associated formational processes but can vary in details and age.”^[2] This context recognizes landform groups that are spatially associated in a unique, recognizable pattern (clustered, oriented, and arranged) indicating a common link (Fig. 2). The link(s) may be similar topography (elevation and relief), composition (bedrock or sediment types), structure (tectonic, crustal deformations), surficial modification (erosional or depositional alterations), etc. and are tangibly different from adjoining landform groups. If landscape subtypes (e.g., different types of mountains) are recognized, the emphasis is on specific geologic or geomorphic attributes (e.g., fault-block mountains vs. volcanic mountains) rather than differences in climate, vegetation, or geography (e.g., the Organ Mountains vs. the Cascade Mountains). A list of common landscapes is shown in Table 1.
3. *Physiographic context:* Landscape—a collection or group of individual landforms that are spatially associated in a unique, recognizable pattern (clustered, oriented, and arranged) indicating common links. The links are not restricted to geomorphic and geologic parameters but may also include geography (where on a continent), native plant communities (desert vs. savannah), dominant cropping or management practices, or some combination of these. If subtypes of a physiographically based landscape are recognized (e.g., different types of mountains), the emphasis is on differences in geography, climate, vegetation or geography, dominant land use practices,^[4] or plant communities, not just geologic or geomorphic attributes. For example, interest has grown in ecosystem or “ecoregions” basis^[5,6] that emphasizes potential native vegetation and/or real-time plant communities or management systems.

Fig. 1 An idealized Landscape painted by Asher Durand, circa 1850.

The ecoregions approach poses both advantages and disadvantages for soils information. Advantages include more overt recognition of climatic nuances and biogeochemical impact of specific plant communities on land management and soil morphology. This approach partitions landscapes into “present-day” or “real-time” environments rather than historical norms. A disadvantage can be an overemphasis on dynamic, potentially ephemeral plant communities that can change dramatically and rapidly, both in geologic and human time frames. Plant communities can change quickly and dramatically with fire, insect or disease infestations, human-caused land use changes, climate shifts, etc. Such vegetation changes can

Fig. 2. 2 A scenic “landscape” (vernacular context) overlook at Waubonsie State Park, Iowa, U.S.A. The view also presents spatially associated groups of individual Landforms that together form several discrete Landscapes (soil geomorphic/technical context): 1) a river valley landscape (a Fluvial Geomorphic setting) composed of natural levees, backswamps, overflow stream channels, etc. during the 2011 floods of the Missouri River (background); 2) a loess hills landscape (an Eolian Geomorphic setting) composed of individual loess hills, loess bluffs, hillslopes, etc. (foreground).

Table 1 A partial list of landscapes commonly used in soil inventory.^[2,3]

Landscapes (broad or unique groups or clusters of natural, spatially associated features)	
Alluvial plain	Kegel karst
Alluvial plain remnant	Lagoon
Badlands	Lake plain
Bajada	Lava field
Barrier island	Lava plain
Basin	Lava plateau
Batholith	Lowland
Bay (coast)	Marine terrace
Bolson	Meander belt
Breached anticline	Mountain range
Breaklands	Mountains
Breaks	Mountain system
Caldera	Ocean
Canyonlands	Outwash plain
Coastal plain	Peninsula
Cockpit karst	Piedmont
Cone karst	Piedmont slope
Continental glacier	Plains
Delta plain	Plateau
Dissected breaklands	Rift valley
Dissected plateau	River valley
Drumlin field	Sandhills
Dune field	Sand plain
Estuary	Scabland
Everglades	Sea
Fan piedmont	Semibolson
Fault-block mountains	Shield volcano
Fluviokarst	Shore complex
Fluviomarine terrace	Sinkhole karst
Fold-thrust mountains	Sound
Foothills	Strait
Glaciokarst	Tableland
Gulf	Thermokarst
Hills	Till plain
Ice-margin complex	Tower karst
Intermontane basin	Upland
Island	Valley
Karst	Volcanic field

occur much faster than subsequent soil changes resulting in a lag-offset between prevailing ecosystem and a corresponding pedologic record of it. Examples include: 1) Climate changes: A rise in atmospheric temperature (e.g., hypsithermal interglacial, or other global warming)

can cause the tree line on mountain slopes to climb, such that formerly cold and barren areas become forested. Similarly, some continental proglacial environments (e.g., periglacial) appear to have changed rapidly following the most recent continental glacier “retreat.” 2) Human-caused land use changes, such as conversion of native woodlands to pasture or croplands and back again (e.g., the initial reduction in native woodlands in New England and the Piedmont following European settlement in the 18th and 19th centuries, with a substantial reversal of that trend in the late 20th century). Another example is the radical expansion of sage and mesquite plant communities associated with livestock grazing in the Southwestern United States since the late 19th century. 3) Introduced plant species: Subtle but no less pervasive ecosystem changes in plant community composition can result from human-introduced plant species (e.g., crabgrass, kudzu, bamboo, and lespedeza in the United States). Landscape classifications based on dynamic plant communities or management conditions are susceptible to misrepresentation over time.

Of these confounding contexts, it is the second, geologic/geomorphic context of landscapes that has consistently proven to have the greatest utility for understanding, describing, predicting, and successfully managing soils.^[3] This success stems from an emphasis on the basic architecture and constituents (the form, internal structure, and composition) of the regolith from which the soil is derived and their effect on water dynamics. Consequently, geologic/geomorphic-based landscape classifications are inherently more durable and reflect dominant conditions (longer term equilibrium conditions). Soils do not immediately re-equilibrate to reflect ecosystem shifts. Soils do adjust to longer term (10s to 100s of years) environmental conditions and eventually reflect new ecosystem equilibriums in their morphology and properties.

Landscape classification

The identification and subsequent placement of different types of landscapes into some order or array.

Grouping individual but related landforms into clusters (i.e., landscapes) provides a meaningful, utilitarian, and common sense way to subdivide the natural continuum of the earth’s surface. Historically, landscapes have been defined by transportation, management, or resource circumstances. Each identified landscape establishes a context, a suite of realities that establish land management opportunities and limitations. Areas that present similar restrictions to travel (e.g., mountains) or are subject to similar hazards (e.g., floodplain) give rise to practical groups. In geology and soil science, emphasis has been placed on morphometric and compositional attributes that have useful applications, such as limitations for road or housing construction, opportunities for food or fiber production, or building material extraction. To these ends,

Table 2 Geomorphic process environments and other useful groupings of landscapes.

Geomorphic environments and other groupings: Land-features [landscapes, landforms, and microfeatures grouped by geomorphic process (e.g., fluvial) or common settings (e.g., water bodies)].^[3]

Environments Other	
1	Coastal marine and estuarine (wave, tidal, or shallow marine related)
2	Lacustrine (related to non-fluvial inland water bodies)
3	Fluvial [related to concentrated channel flow (e.g., stream)]
4	Solution (dominated by dissolution and subsurface drainage)
5	Eolian (wind dominated)
6	Glacial (directly related to glaciers)
7	Periglacial (related to non-glacial, cold climate)
8	Mass wasting (mass movement; gravity-dominated)
9	Volcanic and hydrothermal
10	Tectonic and structural (bedrock structures, crustal movement)
11	Subaqueous features (submerged features generally capable of supporting rooted plants)
12	Wetlands (related to vegetated or shallow wet areas, wet soils)
13	Water bodies (permanent water features)
14	Erosional (dominated by non-channel, non-perennial water erosion)
15	Depressional (low area or declivity terms, excludes permanent water bodies)
16	Slope (generic slope forms, geometry, or arrangement rather than process)

traditional geomorphic process environments provide coherent and functional groupings of landscapes (Table 2).

From a soils perspective, geology strongly influences soils by determining: 1) the materials which are present and 2) their internal arrangement and composition. Concurrently, geomorphology strongly affects soils through the processes and dynamics that move and modify the materials present (e.g., removal, transportation, deposition, and/or geochemical alterations). Geomorphic processes deserve special attention in soil science as they modify residuum (in-place materials) and dictate the transportation and redistribution of unconsolidated materials (e.g., alluvium and colluvium). Active geomorphic processes determine present conditions and strongly impact management choices, and thereby provide the practical link between “what is here?” and “how can we successfully manage it?” for specific purposes. Most important to soil geography (soil patterns), geomorphology is an effective basis from which to explain and predict sediment body distribution (where do specific materials or soils start and stop, and where are you likely to find more of the same?).

Much has been written about various geomorphic processes (e.g., glacial and fluvial) from a strictly geologic point of view.^[7,8] Indeed, these processes strongly influence the macroscale structure of landscapes and the natural distribution of the raw materials in which soils form. There is a related, pedologic perspective of soil geomorphology. It encompasses the relatively thin veneer of regolith (unconsolidated materials) and the processes that generate, redistribute, and alter the regolith at or near the earth's surface.^[9–11] Nuances that are of little or no interest to a geologic point of view may be crucial in a pedologic context and have substantial consequences at the human-operative scale. For example, bedrock geology maps commonly omit relatively thin surficial layers (e.g., <1–3 m) of regolith and rarely recognize “thin” but pedologically important eolian inputs (dust and Aerosols; e.g., carbonates) and outputs (deflation removal of fine particles; e.g., the Dust Bowl). Soil geomorphology deals directly with these near-surface layers and includes the hydrologic behavior that profoundly influences ecosystem behavior and soil patterns (e.g., the red-edge effect^[10,12]) in the same zone.

There has been a shift in the United States away from an emphasis on bedrock inventory and toward a greater emphasis on surficial sediments (regolith). This shift has focused attention on finer-scale geologic/geomorphic processes and sediments and leads directly to soils and soil geomorphology. For example, the relatively thin (50–150 cm) volcanic tephra mantle covering much of Idaho and western Montana is rarely captured on geologic maps, yet has much greater influence on timber growth and ecosystem function than does the much thicker, underlying colluvium/residuum of the tectonically derived mountains. Landscape classifications that directly recognize pedo-geomorphic processes and materials need to be developed further and used.

Scale—the hidden landscape qualifier

Project or application scale predetermines the relative size of features or areas that can be recognized (e.g., minimum polygon size) and therefore what constitutes a landscape (i.e., what features and geomorphic processes are recognized). For a given area of land, a continental scale assessment will reflect a different and obviously more generic suite of landscapes than an assessment focused on smaller, more localized areas. Historically, small-scale-dominated (coarse resolution) landscape assessment.^[13–16] In soil geography, some programs also deal with very large areas (e.g., continental) as in Food and Agriculture Organization's soil maps of the world. Other soil inventory or geography programs are much more localized and detailed. In the United States, soil geography scales range from very coarse (continental) to very detailed (Order 1 site investigations; e.g., 1 in. = 330 m). Within that range, generally soil surveys in the United States (e.g., the

National Cooperative Soil Survey) are more locally scaled (e.g., Order 2 county-level surveys, to regionally scaled (e.g., Order 3 reconnaissance surveys^[17]).

The value of (and to) soils in understanding landscapes

Soil is a synthograph. Soil retains a record of both dramatic and subtle geomorphic processes and environmental site history in its properties and morphology.^[10,12,17,18] Soils can thereby be used to decipher the prevailing past conditions, the history of geomorphic processes (how did an area become what it is?), as well as the present environment and soil behavior. This historical imprint serves as a feedback loop whereby geomorphology can shed light on soil geography and properties, and conversely, soils can and are used to confirm or refine geomorphic interpretations of landscapes.

CONCLUSION

Landscapes are an efficient way to subdivide the earth's surface into areas that share common management or resource opportunities and limitations. Organizing landscapes into an array, such as geomorphic process environments, helps to communicate natural relationships useful for land use management and in simply understanding the world around us. Greater scientific effort is needed to denote landscapes by pedogeomorphic relationships that are not adequately addressed by traditional geologic or geomorphic landscapes.

Landscape: Development and Erosion

Jon Harbor

Department of Earth and Atmospheric Sciences, Purdue University,
West Lafayette, Indiana, U.S.A.

Abstract

Landscapes develop as a result of the interaction between rates and patterns of uplift and denudation. Landscape development occurs over timescales that are typically extremely large from the perspective of soil scientists, and the landscape itself is a spatial scale far greater than those tackled in most soil studies. Scientists interested in modern soil erosion processes and controls usually consider the landscape and landscape features as fixed boundary conditions. Sediment yield data demonstrate the importance of linkages between temporal scales and spatial patterns in soil erosion.

INTRODUCTION

Landscapes develop as a result of the interaction between rates and patterns of uplift and denudation. Therefore, styles of landscape development depend in part on rates and patterns of soil formation and soil erosion.^[1] Although the similarity of some aspects of landscape is seen across spatial scales (Fig. 1) and suggests that fundamental balances of erosional and depositional processes are scale independent,^[2] scale issues are extremely important in understanding how soil erosion and empirical data on soil erosion relate to landscape development.

TIMESCALES

Landscape development occurs over timescales that are typically extremely large ($\approx 10^5$ years) from the perspective of soil scientists, and the landscape itself is a spatial scale far greater than those tackled in most soil studies. Thus, scientists interested in modern soil erosion processes and controls usually consider the landscape and landscape features as fixed boundary conditions (slope angles, lengths, and shapes do not typically change over months or years). Jenny's^[3] often-quoted list of factors of soil formation (including climate, organic matter, relief, and parent material) is in fact a list of independent variables controlling spatial patterns of soil erosion over short timescales (Table 1).

However, over thousands to millions of years, rates and patterns of soil formation and erosion are important in controlling the long-term development of landscape form. Over these long timescales if soil accumulation at a site (soil production plus deposition) exceeds soil loss by erosion, then the denudational balance^[4] results in increasing soil thickness, decreasing subsoil weathering,

and a situation where the erosion rate is limited by the effectiveness of the processes transporting soil on the slope. In such transport-limited situations, long-term slope evolution is toward convexo-concave forms that become progressively moderate over time.^[5] In contrast, if the soil accumulation rate is less than the potential soil erosion rate, then weathered material is removed as soon as it is produced and the rate and pattern of weathering limit the amount and pattern of soil erosion. Under such weathering-limited situations, slopes have prominent straight sections and develop over time by parallel retreat in which slope angles are maintained in dynamic equilibrium.^[5]

Thus, over long timescales, soil erosion rates and patterns are not only affected by landscape form but also by a determinant of landscape form.

More generally, as discussed in detail by Schumm and Lichty,^[5] as the timescale of interest changes, what we consider to be relevant, dependent, and independent variables in soil erosion also change (Table 1). Over short timescales, it is irrelevant what the landscape was like when it was first exposed by uplift, or how much time has elapsed since then, and morphometric variables such as relief and slope shape are independent variables in a study of soil erosion. However, on the timescale of landscape development, variables such as relief and valley morphology change over time as a function of the pattern of geomorphic processes, including soil erosion, and so must be treated as dependent variables. Thus, feedback relationships develop between changes in slope form and soil erosion patterns: Soil erosion patterns depend on slope form, but on long timescales soil erosion patterns change slope form, and thus slope form and soil erosion patterns evolve interdependently.

Timescales are also important in soil erosion measurement programs and in the ways in which we use

Fig. 1 Scale and soil erosion features. Topography is approximately fractal^[2] so, without scale indicators, this landscape photo could have been taken from an airplane of a landscape element on the order of 10^2 km^2 , or it could be a close up of a microscale feature on the order of a 10^0 m^2 .

observations of soil erosion processes to make inferences about landscape development. Over short timescales, our understanding of spatial and temporal patterns of soil erosion is based on monitoring erosion plots and on determining sediment yields from watersheds across a range of spatial scales.^[7] Over geologic timescales, our understanding of spatial and temporal patterns of soil erosion is based on depositional records from lake and ocean sediments and also on cosmogenic nuclide techniques.^[8] The cosmogenic nuclide approach is based on the observation that reactions between cosmic rays and minerals within about 2–3 m of the soil or

rock surface produce a range of cosmogenic nuclides within the mineral structure, i.e., the radionuclides such as ^{26}Al , ^{10}Be , and ^{36}Cl . These nuclides accumulate at known rates, and the production rate decreases exponentially with depth below the soil or rock surface. The concentrations of radionuclides in eroded sediments can thus be used to back calculate the amount of time it took for a sample to go from approximately 3-m deep into the surface and thus is a measure of the surface-lowering (soil erosion) rate. The applications of this technique and comparison with other sources of data allow evaluation of the scale of variations in soil erosion rates at different timescales. For example, sediment yields for a hyperarid drainage basin in southern Israel based on a 33-year sediment budget exceed long-term sediment generation rates based on ^{10}Be and ^{26}Al by 53–86%.^[9] In comparison, over a timescale of several decades, different averaging periods in data from 189 gauging stations in the Eastern United States and Canada produced sediment yield variations of 10–50%.^[10] At the shortest timescales, variations in erosion rates increase dramatically; because soil erosion is an episodic process, measurements over periods of days, hours, or even shorter times fluctuate wildly depending on whether or not an erosional event occurs during the measurement period. Thus, soil erosion rate variability decreases as a function of increasing timescale.

SPATIAL SCALES

Sediment yield data also demonstrate the importance of linkages between temporal scales and spatial patterns in soil erosion. In the data from gauging stations in the Eastern United States and Canada,^[10] in addition to temporal variation in sediment yield as a function of the timescale used for averaging, the spatial pattern of sediment yield varied dramatically between averaging periods. If only one averaging period had been used to derive inferences about spatial patterns of soil loss, this could lead to misleading conclusions concerning longer term patterns of landscape development. Thus, understanding spatial patterns of soil erosion for application to landscape development requires the use of information on soil erosion patterns at the appropriate temporal scale.

Table 2 Impact of spatial scale on denudation rates.

Basin area (km^2)	Mean denudation rate ($\text{mm}/1000 \text{ yr}$)
3×10^{-1}	12,600
3×10^0	2,550
8×10^1	220–60
3.9×10^3	100–30
3.7×10^4 – 3.3×10^6	60–30

Source: Adapted from Schumm & Lichty.^[6]

Spatial scale also has a significant impact on soil erosion process and rate data. Soil erosion rates, as indicated by sediment yields back calculated to derive denudation rates (Table 2), typically are greatest at small spatial scales. This important observation is largely because of differences in the relative magnitudes of processes operating at different spatial scales and on sampling techniques. At larger spatial scales, soil erosion, as measured by sediment yield, includes both erosion and deposition. Loss of sediment to deposition on hillslope sections with decreasing gradient and on floodplains significantly reduces net soil loss rates from a landscape,^[7] and this pattern of erosion and deposition is important for landscape form development. In contrast, soil erosion studies at plot scales rarely include areas of deposition and are dominated by studies of small-scale soil detachment and transport processes. Thus, from a landscape development perspective, the extrapolation of rates from small spatial scales to predict landscape change rates is likely to result in the significant overestimation of rates and styles of landscape change.

Landscape: Elements

Douglas Wysocki

Research Soil Scientist, National Soil Survey Center, Lincoln, Nebraska, U.S.A.

C. William Zanner

University of Nebraska, Lincoln, Nebraska, U.S.A.

Abstract

Soils are landscape entities that possess geomorphic, geometric (surface form), and geochemical character. This is not mere scientific coincidence but reflects the link between landscape evolution and soil formation. Landforms are the basic units that combine to form a landscape. Various often-episodic processes create landforms. Thus, landforms in a landscape may not be comparable to or repeated in other landscapes.

INTRODUCTION: SOIL LANDSCAPES—THE INTRICATE LINK

Landscapes and soils form an intricate, 3-D continuum at the earth's surface. The soil landscape continuum displays remarkable diversity and complexity. To more easily comprehend and effectively manage the soil landscape, we recognize and delineate individual soils. To recognize a soil, we must identify three boundaries—upper, lower, and lateral. The upper soil boundary, the atmosphere to earth's surface interface,^[1] is readily apparent. The lower soil boundary is less distinct, and more difficult to define, but can be an abrupt contact (e.g., bedrock layer) or a gradational change with depth. Soil processes (biologic activity, water and solute transmission, and rooting depth), however, respect no specific limit (e.g., 2 m) and often extend several meters.^[2] Lateral soil boundaries are of greatest concern, as they define soil arrangement and extent on landscapes. Soils occur in a landscape sequence, known as a catena^[3,4] or a soilscape.^[5] No physical interfaces or barriers necessarily separate soils in a catena, rather soil properties change gradually with distance. Soil differences arise from combined geomorphic, atmospheric, and biologic processes that provide energy and material inputs. Soil boundaries often coincide with natural landscape breaks. Soil and landscape unit boundaries occur at observable, predictable positions where energy and mass transfers are restricted or controlled by landscape form, internal structure, or both.^[6] Soil formation and landscape evolution are coeval. Soils originate and evolve by processes that also drive landscape evolution. For example, erosion and deposition concurrently consume and construct adjacent hillslope elements. Erosion partially or entirely removes soil in higher areas. Deposition blends eroded sediments with existing soil or furnishes fresh parent material (sediment) by burying lower areas. Soils are a landscape history and a portrait of geomorphic process.

LANDSCAPES, LANDFORMS, AND BASIC LANDSCAPE UNITS

Landscape unit boundaries include slope gradient inflections, slope shape or aspect differences, contacts between landforms of different origin and composition, and near-surface contacts between rock types or sediment bodies.^[6] Note that landscape unit boundaries are visible or inferable by surface form, are defined and identified independent of soils, and occur in all landscapes. The strong linkage between soils and landscape units allows consistent, reliable, and economical soil prediction.

Simply, a landscape is a geographically associated landform assemblage visible in a single view.^[7,8] Four primary agents (water, wind, ice, and gravity) independently or in combination create and alter landforms through episodic and spatially focused processes. Landforms are earth surface features that have a specific origin, form, and composition; they are the basic landscape unit. Landforms may originate through a single, time-constrained process (e.g., a glacial advance). Generally, however, landforms originate through various processes acting over geologic time. Most landscapes contain landforms of different ages and origins. Landform kind and location depend upon geomorphic processes and history. Soil landscape relationships, therefore, are specific to a geographic region. Specific soil-landform knowledge is only transferable to landscapes with similar geomorphic history.

HILLS AND HILLSLOPES

Hills possess three valuable characteristics of a fundamental landscape unit. Hills occur in most geomorphic settings, are easily identified, and contain segments with consistent linkage to soil occurrence. Hills may initially form through constructional processes (e.g., dunes—eolian

deposition, kames—glacial deposition, and fault scarps—tectonic uplift). Fluvial erosion and deposition, however, are the overarching processes that sculpt and create hills. Gravity and the hydrologic cycle are the universal forcing mechanisms in hillslope evolution and soil formation.

HILLSLOPE DESCRIPTION

A few geometric and geomorphic descriptors accurately define hillslope characteristics. Primary descriptors include slope gradient, aspect, shape, complexity, position, and geomorphic components. Slope gradient is the ground surface inclination from a horizontal plane. We express slope gradient as degrees (e.g., 45°) or as a rise/run percent (e.g., 100%). Aspect, the direction a slope faces, is a compass azimuth (e.g., 225°) or a cardinal direction (e.g., southwest). In the northern hemisphere, north and east facing slopes are cooler and moister than south or west facing slopes. Noted soil differences occur due to aspect.^[9–11]

Slope shape refers to surface form. The vertical profile (upslope and downslope) and elevation contour (across slope) are either straight (linear) or curved. If curved, the shape is convex (upward or outward curve) or concave (downward or inward curve). Combining the vertical profile and across slope shape yields nine possible 3-D forms (Fig. 1). Slope shape influences water movement both overland and throughflow. A slope linear in both profile and contour produces parallel, lateral flow. A convex slope in both profile and contour causes divergent flow, and a slope concave in both profile and contour creates convergent flow (Fig. 1). Slope complexity refers to periodicity and downslope flow path (Fig. 2). Simple slopes are smooth with few undulations, or flow obstructions, and few

Fig. 1 Slope shapes with surface flow lines based on profile and contour.

deposition points. Complex slopes contain substantial irregularities or undulations that interrupt surface flow, impede runoff velocity, and create deposition points.

GEOMORPHIC DESCRIPTORS

Landscape elements along a hillslope profile are distinguishable by shape, position, erosion degree, and sediment occurrence and characteristics.^[12] Ruhe^[13] defined five slope elements: 1) the summit, 2) shoulder, 3) backslope, 4) footslope, and 5) toeslope (Fig. 3). The summit is the nearly level, uppermost element. Summit soils commonly exhibit the greatest profile development in a landscape. The shoulder is the convex element below the summit. The shoulder undergoes greater erosion than the summit. Soils tend to be similar to, but thinner than those on the summit, and may be vertically compressed or truncated. The shoulder descends to the steepest and linear slope element, the backslope, where surface runoff and sediment transport are at a maximum. Backslope soils display less development than summit or shoulder soils. The backslope descends to a concave element, the footslope. Surface water flow velocity and transport capacity decrease at the footslope, which results in deposition. Footslope soils tend to accrete upward, are wetter, and lesser developed than soils on higher positions. The footslope merges downslope with the toeslope, which is predominantly linear or slightly concave. The comparatively low slope gradient and

Fig. 3 Hillslope profile elements.

Source: From Ruhe.^[8] ©1975.

position promote alluvial processes as either surface run-on or stream inputs. Toeslope soils tend to be deep, comparatively moist, and composed of alluvial sediments. Together the five slope elements provide a succinct, but eloquent set of landscape units that effectively describe both hillslope positions and soil location.

The 3-D landscape relationships require additional geomorphic descriptors. Ruhe^[8,14] formalized four geomorphic components for open drainage systems the interfluvial, head slope, side slope, and nose slope (Fig. 4). Wysocki, Schoeneberger, and LaGarry's study^[6] has added a fifth, the base slope (Fig. 4). The interfluvial, the uppermost landscape area, is the oldest, most stable component. Regionally, it contains the most well-developed soils. Below the interfluvial, landscapes can undergo backwearing (erosion), which initiates at stream heads and is focused by overland flow. Head slopes, side slopes, and nose slopes direct overland flow: converging (head slope), parallel (side slope), or diverging (nose slope). Flow direction in turn determines erosion and sediment transport. Below the nose slope, head slope, or side slope is the base slope^[6] where sediment deposition or decreased transport capacity dominates over erosion, which results in a colluvial apron.^[15]

Other landscapes (mountains, terraces, and plains) have dynamics and complexity that warrant distinct descriptors. Mountains embody a unique geomorphic setting of size and slope complexity. Mountainsides are complex slopes up to thousands of meters long with steep slope gradients, highly diverse sediment mantles, and elaborate, near-surface hydrology. Mass movement processes and features are more prevalent than in hills. Deep soils, however, may exist over hard rock on steep slopes or mountainsides.^[16,17] Consequently, Wysocki, Schoeneberger, and LaGarry^[6] proposed distinct geomorphic components (e.g., mountaintop, mountainflank, and mountainbase) for mountains (Fig. 5).

Low slope gradient and limited relief characterize two landscape forms. These are terraces and plains. Terraces are

Fig. 4 Geomorphic components: hillslopes.

Source: From Wysocki, Schoeneberger, et al.^[6] ©2000 CRC Press.

Fig. 5 Geomorphic components: mountains.

Source: From Wysocki, Schoeneberger, et al.^[6] ©2000 CRC Press.

level or gently inclined landforms that border a stream, lake, or sea. Stream terraces develop via alluvial deposition and/or erosion, rather than slope processes. Two geomorphic components exist for terraces (Fig. 6). The tread is a broad, generally level terrace surface. Treads can extend laterally for many kilometers.^[18,19] The riser component is an escarpment that separates terrace or flood-plain levels. The riser is a short, steep slope cut into sediments below the upslope tread. Risers can extend for considerable distances up and down a valley but may be only tens of meters across. Risers mark an abrupt change to a lower hydrologic base level, which suppresses the water table along the higher tread margin. Soils above and adjacent to a riser have better drainage than those farther away do. Daniels et al.^[20] called this the “red edge effect.” Risers can separate soils, sediments, and geomorphic surfaces of significant age difference.

A plain is any landform with limited relief and slope gradient regardless of origin. Lacustrine, coastal, and

Fig. 6 Geomorphic components: terraces.

Fig. 7 Geomorphic components (provisional): plains.

Source: From Wysocki, Schoeneberger, et al.^[6] ©2000 CRC Press.

glacial processes can produce distinctly low-relief plains with limited outlets for surface runoff. Low potential energy to drive water flow is the common, critical geomorphic character. Political interest and recognized ecological value of wetlands and hydric soils^[21] highlight the need for unique geomorphic components to describe plains. Small elevation differences (e.g., 15 cm or less) on a plain can result in significant soil and hydrologic differences.^[22] Provisional geomorphic components have been proposed^[15] for plains. Broad, low slope gradient (1%), low-relief areas on plains are “talfs” (Fig. 7). A “rise” is a slightly elevated plain component that exhibits subtle but significant relief (i.e., microhigh) and/or slope gradient differences. A rise is marked by observable soil and ecological differences compared to the adjacent plain or talf. Closed depressions within a plain are termed “dips.” Low relief restricts potential energy in plains. Drainage systems tend to expend energy by transport rather than erosion or incision. Consequently, drainage networks tend to be weakly to moderately developed with limited channel incision, except in active uplift areas. Precipitation tends to pond locally due to low hydraulic gradient and extended paths to outlets. Runoff is comparatively slow both above and below ground. These conditions favor organic matter accumulation (e.g., organic soils and upland bogs) and hydric soil formation.

CONCLUSION

Soils are landscape entities that possess geomorphic, geometric (surface form), and geochemical character. This is not mere scientific coincidence but reflects the link between landscape evolution and soil formation. Landforms are the basic units that combine to form a landscape. Various often-episodic processes create landforms. Thus, landforms in a landscape may not be comparable to or repeated in other landscapes. The most widely known and used geomorphic-based landscape

elements (summit–shoulder–backslope–footslope–toeslope; interfluvial–side slope–head slope–nose slope–base slope) are based on hillslope process and form and incorporate both geomorphic and soil-forming processes within their definition. These term sets succinctly convey landscape position, surface form, and water flow direction and indicate soil occurrence. The terms are most applicable and work well in moderate relief landscapes. Mountainous terrain and low-relief plains warrant greater scientific study and need additional geomorphic descriptors.

Landscape: Relationships

Timothy A. Quine

School of Geography and Archaeology, University of Exeter, Exeter, U.K.

Abstract

Tillage erosion is inextricably linked to landscape characteristics. The magnitude of tillage erosion rates is determined by the characteristics of the landscape and the spatial variation in soil redistribution by tillage contributes to the evolution of spatial variation in the landscape. The dynamic relationships between tillage erosion and landscape are, therefore, addressed under the headings *landscape sensitivity* and *landscape heterogeneity*. Sensitive landscapes are topographically complex or have a high density of field boundaries, or display both characteristics. Tillage erosion contributes to the evolution of landscape heterogeneity through creation of distinctive landforms, such as lynchets, terraces, and field boundary steps, and through progressive but relatively rapid redistribution of soil from spurs to hollows. The resultant variability in soil properties is an important influence on crop production and water erosion.

LANDSCAPE SENSITIVITY

Tillage erosion potential, described by the tillage transport coefficient, is controlled by and may be predicted from cultivation practice; however, in order to determine rates of tillage erosion, this erosion potential must be combined with information concerning landscape sensitivity to tillage erosion.

Tillage erosion occurs where the outflux of soil (usually downslope) due to tillage translocation exceeds the influx of soil (usually from upslope) due to tillage translocation—accumulation occurs under the opposite conditions. Net soil loss and gain due to tillage erosion are focused on areas in the landscape with discontinuous or rapidly changing flux. Therefore, high landscape sensitivity to tillage erosion is found in landscapes with complex within-field topography or where there are numerous field boundaries located across steep slopes. In general terms, for landscapes of the same average slope angle, complexity and sensitivity to tillage erosion are inversely related to the distance between slope crest and valley, and for landscapes with similar crest to valley distance, relative sensitivity to tillage erosion will be proportional to average slope angle (Table 1).

The location of such sensitive landscapes is determined by lithology and long-term erosion history and, consequently, strong spatial variation in landscape sensitivity to tillage erosion exists even where there is relatively little variation in tillage erosion potential. In a study of topographic controls on medium-term soil redistribution on five agricultural fields in the United Kingdom, slope curvature (and, by implication, tillage erosion) dominated soil redistribution on the four fields underlain by sands, siltstone, and chalk, whereas on the field underlain by clay with flints, no such relationship was identified.^[1] All the fields were

subject to similar cultivation practice and the differences observed represent variation in landscape sensitivity due to lower topographic complexity. This is most clearly reflected in the range of slope profile curvatures: On the clay soils, the range was only 25% of the smallest range observed on the other fields.

High sensitivity landscapes include strongly rolling glacial till lands, incised loess plains, and dry valley systems (Fig. 1).

LANDSCAPE HETEROGENEITY

The discussion of landscape sensitivity has addressed the control that large-scale landscape heterogeneity exercises on spatial variation in tillage erosion rates. Changing the scale of examination to the field/subfield scale sees a reversal in causation and the control of tillage erosion rates on the existence and degree of heterogeneity may be examined. Two aspects are considered: landform creation and landform modification.

Landform Creation

The creation of distinctive landforms provided some of the first evidence for the importance of tillage erosion as a pedo-geomorphic process on agricultural land^[2] and “monuments” of tillage erosion (Fig. 2) associated with boundaries of cultivation may be seen in a wide range of agricultural systems.

Field boundaries form lines of zero tillage flux. In landscapes where relatively steep slopes are divided by cross-slope boundaries, these lines of zero flux represent *significant* flux discontinuities with high influx and zero

Table 1 Indicative mean soil redistribution rates due to tillage erosion.

Soil redistribution rates (t ha ⁻¹ yr ⁻¹)					
Distance (m)	Maximum (slope 10°)	Maximum (slope 5°)	Maximum (slope 3°)	Slope change from 3° to 10° or from 10° to 3°	Slope change from 3° to 5° or from 5° to 3°
50	18	9	5	12	4
40	22	11	7	15	4
30	29	15	9	21	6
20	44	22	13	31	9
10	88	44	26	62	18
5	176	87	52	124	35

Notes: 1) An annual tillage transport coefficient of 500 kg m⁻¹ has been used—This is indicative of one typical mouldboard plough operation and two supplementary operations, e.g., disking and harrowing. 2) These are mean rates and mask significant smaller scale variability. Where the distance refers to the land surface either from the upslope boundary to the location of maximum slope or over which slope angle increases, the rates are mean rates of erosion over the specified distances. Where the distance refers to the land surface either from the location of maximum slope to the downslope boundary or over which slope angle decreases, the rates are mean rates of accumulation over the specified distance.

outflux on the upslope side and high outflux and zero influx on the downslope side. This flux discontinuity results in soil accumulation adjacent to the boundary in the upslope field and soil loss adjacent to the boundary in the downslope field with the consequent formation of a linear step along the boundary line (Fig. 3). Such steps are near universal features of agricultural landscapes:

1. Where fields are or have been narrow contour strips, bench terraces,^[3] or strip lynchets are created—the latter have provided landscape archaeologists with evidence of past land use.
2. When larger fields are located on steep slopes subject to mechanized agriculture, then the steps may develop into large changes in slope—for example, steps 3–4 m high have been identified in the Palouse region of the Pacific Northwest of the United States.^[2]
3. Even in landscapes where water erosion processes dominate geomorphological evolution and cultivation is undertaken by hand, discontinuity in cultivation leads to step formation^[4] and such steps can become

Fig. 1 A landscape of high sensitivity to tillage erosion—seasonally dry valleys and rolling hills near Cordoba in southern Spain. This landscape is also highly sensitive to water erosion.

unstable and act as foci for small-scale mass failure and pipe or gully initiation (Fig. 4).

The formation of these distinctive landforms is associated with local change in soil properties associated with accumulation and loss of plow soil. In landscapes in which rolling topography is divided into relatively large fields, this may have relatively little impact on field-scale soil variation and productivity, although

Fig. 2 Dr. Dino Torri (shown) and Dr. Paolo Bazzoffi coined the phrase “monuments of tillage erosion” to describe features such as this relict land surface surrounding a solitary pine on a strongly convex hill in Tuscany, Italy.

Fig. 3 Evidence of tillage erosion is widely seen in large banks at contour field boundaries on sloping agricultural land subject to mechanized agriculture. This example is from Aarslev in Denmark. **Source:** From Papendick & Miller.^[2] ©1977.

boundary zones of depleted crop production are often visible. However, where moderately steep slopes are divided into narrow strips and rapid lynchet or terrace development takes place (Table 1), the landscape will become characterized by large variation in soil properties over small distances.^[5–7] The significance of this variation will be dependent on the nature of the subplow horizons. If the subplow material is nutrient rich and easily weathered the impact on soil productivity may be small^[7] but if the subplow soil is significantly less productive than the plow soil, significant variation in crop production over distances of a few meters can be expected^[6,8] and a large proportion of the available agricultural land may become unproductive.

Landform Modification

The effect of differential flux on complex landforms is in marked contrast to the effect of zero flux on relatively

Fig. 4 Water erosion is the dominant erosion process on agricultural fields in the rolling hills region of the Loess Plateau but, even here, tillage steps develop at the lower boundaries of fields and these can be focused for mass failure and pipe or gully initiation. **Source:** From Quine, Govers, et al.^[4]

Fig. 5 Tillage erosion of soil from the ridges and transport into the hollows in this field in Minnesota, U.S.A, has led to the development of visible strong within-field spatial variation in soil properties. In this case, the land user is attempting to remediate the problem by manuring the convexities.

simple landforms. While the latter leads to landform creation, the former leads to gradual landform obliteration, although the rate is such that landform modification will usually be a more appropriate description. In essence, tillage erosion leads to a gradual smoothing of the topography and reduction in relief intensity. Convex slope elements are subject to greatest soil loss (Fig. 2) and concavities such as seasonal or relict channel lines are subject to soil accumulation. Tillage acts like a conveyor belt transporting soil from crest to hollow leading to gradual infilling of the hollow and reduction in crest altitude. This creates important synergy with water erosion processes.

This homogenization of landform is, nevertheless, associated with an increase in landscape heterogeneity because of the associated increase in soil variability. Differences in soil properties between crest and hollow become more marked as (topsoil rich) plow soil accumulates in the hollows leading to the formation of overdeepened Ap horizons, while the plow soil on convexities becomes diluted by subsoil inclusion (Fig. 5) and depleted in surface-derived material (e.g., organic matter and surface applied nutrients).^[9] Even where no net soil loss occurs on linear slopes below convexities, downslope tillage translocation of soil from the crest leads to soil depauperation (due to subsoil incorporation).^[10,11]

Systematic spatial variation in water movement and availability driven by topographic controls on hillslope hydrological processes will combine with this erosion-produced systematic soil variability to create a landscape of strong within-field spatial variation in plant growing conditions (Fig. 6)^[12,13] that may be economically very significant where water supply is a limiting factor for crop growth.

While landform modification is usually the most appropriate term, landform obliteration may take place

Fig. 6 Spatial variation in soil properties combines with hillslope hydrology to create significant spatial variation in conditions for crop growth seen in variation in time of flowering in this oilseed rape crop in Devon, U.K.

Source: From Quine & Zhang.^[13]

where slope curvature is very high, slopes are short and implements are large. Under these conditions, planning of landforms^[14] can result in much more rapid landform evolution and strong variation in soil properties over very short distances.

Taiwan Slope Land Disaster Prevention Association, Taichung, Taiwan

Abstract

Landslide and slope failure are soil mass movement that cause costly damage to property, structures, and even human life. In this entry, “slope failure” is used when the interface between the moving soil mass and the stationary underlayer is unclear and the moving speed is fast. The term “landslide” is used when the interface is clear or gradually varied and the moving speed is relatively slow. The former is usually for small-scale surface failure, while the latter is for large-scale movement of soil mass. The occurrences of both slope failure and landslide are related to the soil types and properties. Also, mass movement becomes flow, such as debris flow, if the soil mass is deformed during the movement. First, the mechanisms that trigger the slope failure, including surface saturation, piping, pressurized groundwater, surface erosion, flow, and earthquake are discussed. The major differences between landslide and slope failure are also identified. Second, the characteristics, classifications, investigation, and mitigation measures of landslide are illustrated. Finally, the distinction between debris flow and mudflow is explained. In addition, three important conditions required for the initiation of debris flow are clearly identified.

INTRODUCTION

Landslide and slope failure are soil mass movement causing costly damage to property, roads, utilities, structures, stream channels, and many times human life. In geomorphology, there are many different classifications for soil mass movement. In general, “slope failure” is used when the interface between the moving soil mass and the stationary underlayer is unclear and the moving speed is fast. The term “landslide” is used when the interface is clear or gradually varied and the moving speed is relatively slow. Also, mass movement becomes flow, such as rock flow, debris flow, and earth flow, if the soil mass is deformed during the movement.

The occurrences of both slope failure and landslide are related to the soil types and properties. Slope failure may occur when a rainstorm saturates the soil layer, and mechanisms such as piping, pressurized groundwater, and/or earthquake trigger it. Landslide is frequently initiated by the weakened cohesive soil or clay layer with a rising groundwater table due to rainfall.

In nature, the distinction between landslide and slope failure sometimes is not very clear. The scale of the failure and movement speed can be used to distinguish them. Slope failure is for rapid, small-scale surface failure and landslide for slow, large-scale movement of soil mass. Mudflow is an extreme case of the debris flow. It mainly carries sediment finer than coarse sand (2 mm).

SLOPE FAILURE

Slope failure refers to the abrupt failure of steep hill slope due to the effects of seepage water and the weight of soil mass. The displacement of the soil mass varies from more than 10 to several hundred meters. Slope failure occurs when a rainstorm saturates the soil layer and one or more of the following mechanisms usually trigger it.

Surface Saturation

When there is a dense and impermeable subsurface layer, a saturated surface may form after a prolonged rainstorm. Water saturation increases the weight of the surface layer and decreases the soil strength. On a steep slope, the weakened surface layer can easily initiate a slope failure. This is the most common type of slope failure, and it usually occurs near the peak of the storm. Although this mechanism is simple, the variability of the soil and geologic properties on the landscape as well as the variability of the rainfall pattern makes it very difficult to predict when and where the slope failure may occur.

Piping

This type of slope failure occurs in sandy soils where interflows or piping is easily formed. First, piping causes the seepage flow to increase suddenly, and a small slope failure

occurs at a certain point on the hill slope. Gradually, larger slope failure occurs above the initial point of piping-induced slope failure. This process may occur at many parts of a hill slope. This type of slope failure starts during the early stage of a rainstorm.

Pressurized Groundwater

This type of slope failure occurs in the places where surface soil layer is thick and the groundwater is easy to concentrate. The mass movement occurs in the valley-shaped soil layer with little disturbance. Due to the topographical and geological conditions, slope failure occurs near bedrock due to the decrease of effective stress from the pressurized groundwater.

Surface Erosion

Initially, a small slope failure occurs at a certain point near the upper portion of the slope surface. When the soil mass of the small slope failure flows down the slope, it may trigger additional down slope failure through surface erosion or failure of saturated surface soil. This type of slope failure usually occurs on the shallow surface layer for a steep, valley-shaped slope.

Flow

When the coarse and loose surface soil layer, containing fine grains and organic material, is saturated, it loses its strength and starts to flow. Some of the material may move as clods, but most of the material tends to move as an earth flow. This type of slope failure usually occurs on bare lands or grass slopes with gentle gradient.

Slope failures may also be induced by an earthquake. According to the analysis of aerial photographs by the Soil and Water Conservation Bureau in Taiwan, slope failures occurred at 2365 locations covering a total area of 14,347 ha in central Taiwan on September 21, 1999, due to a devastating earthquake (100-year return period), 7.3 on the Richter scale.

Several slope failures occurred along the Chin-Shui River as a result of the September 21 earthquake, resulting in an upstream impoundment of water, below the village of Tsao-Ling. The minimum crest of the slope failure at the impoundment was estimated to be approximately 540 m, with an estimated total storage volume of about 43 million cubic meters. This location has a long history of slope failures caused by either earthquakes or heavy rainfall, resulting in the impoundment of water and subsequent breach outflow causing downstream damage and loss of life. The massive slope failure covered an area of 620 ha (about 5 km along the river channel) and with an amount of 126 million cubic meters of deposited material.

Table 1 shows the major differences between landslide and slope failure indicated by Watari.^[1] However, the

Table 1 Differences between landslide and slope failure.

	Landslide	Slope failure
Geology	Occurs in places with particular geology or geological formation	Seldom related to geology
Soils	Moves with cohesive soil as slip surface	Frequently occurs even in sandy soils
Topography	Occurs on gentle slopes of 5–30°, especially if the upper portion is plateau topography	Frequently occurs on the slopes steeper than 30°
Occurrence	Occurs gradually and continuously	Occurs suddenly
Moving speed	Usually low at 0.01–10 mm/day	High speed, greater than 10 m/s
Surface deformation	Soil moves with original shape and little disturbance	Soil mass being disturbed
Provoking causes	Greatly affected by groundwater	Affected by rainfall, especially rainfall intensity
Scale	Large scale, between 1 and 100 ha	Small scale
Warning signs	Cracks, depressions, upheavals, groundwater fluctuations occur before the landslide	Seldom has symptoms and slips down suddenly

Source: Revised from Watari.^[1]

dividing slope between landslide and slope failure (30°) and the high moving speed of slope failure (>10 m/s) are modified.^[2]

LANDSLIDE

Landslide usually occurs continuously or intermittently on gentle slopes at a large scale (usually greater than 1 ha). Sometimes, landslide may shift to an abrupt slope failure or even becomes a debris flow.

The characteristics of landslide include the following:

1. It usually occurs in places with particular geology.
2. The slip surface usually occurs at layers with clay or clayey soils. The movement is mainly induced by the groundwater effect.
3. It usually occurs on gentle slopes. More than 50% of the landslide occurs on slopes with slope angle less than 30°.
4. The large-scale soil mass (1–100 ha) usually moves with its original shape with little surface disturbance. Cracks, depressions, upheavals, and groundwater fluctuations have been observed before the landslide, but in general, landslide is a long-term, continuous, and slow soil mass movement.

5. The moving speed of landslide is usually low at 0.01–10 mm/day. The movement can be either continuous or intermittent. However, the final slope failure may occur rapidly.

The distribution of landslide is highly influenced by the geological structure. In Japan, it usually occurs in 1) Neogene (new tertiary); 2) tectonics; 3) areas affected by the volcanic activity-induced upheavals, depressions, or areas influenced by strong geothermal gradients from volcanic gas or hot springs; 4) areas with the Eocene (old tertiary) shale and tuff belt containing cap rock, or areas along the fault or with coal pit. But the areas with a low degree of consolidation for the quaternary deposits seldom have this type of landslide. In England and North European countries such as Sweden and Norway, landslides occurring in areas with thick clay deposits are of major concern.

Fig. 1 shows the landslide that occurred at Keelung–Hsieh section of Highway 3 in Taiwan on April 25, 2010, due to a dip slope failure (the beds in the slope were inclined subparallel to the slope surface). The total amount of the sliding material was about 100,000 m³. It took the Highway Bureau about 2 months to restore the traffic. According to the field observations, the slip surface occurred at a clay layer, which was consistent with the second characteristics of landslide mentioned above. The rock formations above and below the slip surface are sandstone and shale layers, respectively.

Classifications of Landslide

Landslide can be classified according to the characteristics of geologic structure, formation features and history of landslide development, type of movement, and shape of

Fig. 1 Extreme landslide disaster on Highway 3 in Taiwan on April 25, 2010.

Source: Photo by National Airborne Service Corps, Ministry of the Interior, Taiwan.

longitudinal profile for slip surface.^[3] One of the most famous landslide classifications was given by Varnes.^[4] For example, based on the type of movement, landslide can be classified into the following: falls, topples, rotational and translational slides, lateral spreads, flows and complex movement, etc. Similar information also can be found in U.S. Geological Survey “fact sheet” online.^[5]

Causes of Landslide

Besides geological factors, landslide may be triggered by many causes but can be generally classified into two categories, i.e., natural phenomena and human activities. The natural triggers of landslide include rainfall, snowmelt, groundwater, earthquake, channel incision, and hill slope failure. The human-induced factors include cut and fill of roadways, mining, excavation of tunnels, and construction of reservoirs.

Investigation of Landslide

Investigations of landslide include the collection of information on topography, soil, and geology; monitoring the weather, groundwater, and movement of the soil mass; and the performance of slope stability assessment for slope failure hazard potential. More detailed procedure can be found in the nomograph published by Japan landslide society.^[2]

Landslide Mitigation Measures

Landslide mitigation measures are selected based on the provoking causes. In general, they can be classified into two categories, i.e., the precaution measures and the prevention measures. The precaution measures rely on a detailed geologic and hydrologic database to predict the potential for landslide occurrence and a real-time monitoring system to provide information such that warning can be issued when a slope failure event becomes imminent. The prevention measures include the control works and the restraint works. The control works are used to eliminate the provoking causes of landslides. The restraint works are used to increase the shear strength of the soil layers and to slow down the movement of the soil mass. Fig. 2 shows the detailed landslide mitigation measures.

DEBRIS FLOW AND MUDFLOW

Debris flow is a mixture of water, sand, and large solid particles. It has strong impacting and destructive forces as it moves downstream a channel. Fig. 3 shows a severe debris flow disaster that occurred on October 9, 1973, near the Zhiban bridge, Zhiban Creek in eastern Taiwan. Zhiban Creek basin has abundant hot spring

Fig. 2 Landslide mitigation measures.

resources. The gravel/sand, slate, and metasandstone layers were identified based on the drilling information. The debris flow was caused by the heavy rainfall from Typhoon Nora. The amount of deposited sediment was so large that the surface of the deposited material almost reached the lower surface of the bridge deck. As shown in the figure, the temple was almost completely buried.

Mudflow is an extreme case of the debris flow. It mainly carries sediment finer than coarse sand (2 mm) but sometimes also a small amount of rock fragments. There are two types of mudflow.^[6] The first type occurs in the active volcano areas, and it contains volcanic ash. The second type occurs in the tertiary or dormant volcano areas, and it contains the old volcanic ash and weathered tephra. The moving speed of the mudflow is usually at least twice faster than the ordinary debris flow, which contains more coarse particles.

In general, the initiation of debris flow is related to the following three conditions: 1) available loose solid material; 2) steep slope gradient; and 3) heavy rainfall. The loose

Fig. 3 A severe debris flow disaster near the Zhiban bridge in Taiwan due to the heavy rainfall from Typhoon Nora (October 9, 1973).

solid material may be due to the prior landslides, land creeps, typhoons, earthquakes, and volcanic eruptions. The gravitational force associated with steep slopes is an important driving force for the initiation of debris flow. An intensive rainstorm is usually the triggering factor for the formation of a debris flow.

Abstract

This entry provides a short background to the international and national soil law and outlines moves to promote reform of soil law including progress made on developing appropriate frameworks for successful management of soil as an ecological element.

INTRODUCTION

At a national level, soil law means a body of law to promote soil conservation enacted by a legislature, e.g., an act, decree, regulation, or other formal legal instrument that is legally enforceable. Soil law, or “soil legislation” as it may also be referred, includes those laws that have primary responsibility for soil conservation, soil and water conservation, and land rehabilitation. They are generally characterized by provisions to mitigate and manage soil erosion and soil degradation and methods to conserve soil resources. Internationally, the legal framework for the conservation of soil can include conventions, protocols, agreements, and covenants, which are expressed to be legally binding. Worldwide, soil law is managed by a variety of legal and institutional systems, which are the individual organizational and operational regimes that have the administrative authority over soil.

WHY LAW FOR SOIL?

Soil bodies are effectively large ecosystems and comprise fundamental components of the earth's biodiversity. Soil is thus seen as the basis for the conservation of terrestrial biological diversity and the sustenance of all terrestrial organisms, including people. The widespread soil degradation as a result of human use of soil provides the imperative for enactment of soil law. The ever-increasing demand for food by rapidly growing populations in many countries in the past few decades has exerted increasing environmental stress on the soil leading to widespread soil degradation.^[1] The following definitions provide the context for soil law.

Soil

Soil forms an integral part of the earth's ecosystems and is situated between the earth's surface and bedrock. It is

subdivided into successive horizontal layers with specific physical, chemical, and biological characteristics. From the standpoint of history of soil use, and from an ecological and environmental point of view, the concept of soil also embraces porous sedimentary rocks and other permeable materials together with the water that these contain and the reserves of underground water.^[2]

Soil Degradation

Soil degradation is a loss or reduction of soil functions or soil uses. It includes aspects of physical, chemical, and biological deterioration, including loss of organic matter, decline in soil fertility, decline in structural condition, erosion, adverse changes in salinity, acidity, or alkalinity, and the effects of toxic chemicals, pollutants, or excessive flooding.^[1]

The Sustainable Use of Soil

The sustainable use of soils preserves the balance between the processes of soil formation and soil degradation while maintaining the ecological functions and needs of soil. In this context, the use of soil means the role of soil in the conservation of biological diversity and the maintenance of human life.^[3]

INTERNATIONAL LAW AND SOIL

International environmental law is an essential component for setting and implementing global, regional, and national policy on environment and development. There is an increasing recognition of the role of international environmental law to overcome the global problems of soil degradation, including its ability to provide a juridical basis for action by nations and the international community.^[4] A number of international and regional instruments introduced in the past years contain elements that can

contribute to achieving sustainable use of soil. None are sufficient on their own. Some of the instruments could assist by promoting the management of some of the activities that can control soil degradation. However, this role is not readily apparent except for those that include provisions specifically directed to soil (e.g., see Article IV “Soil”—1968 *African Convention on the Conservation of Nature and Natural Resources*, final revision text adopted by the African Union Assembly on July 11, 2003).

Declarations

A number of non-binding declarations and charters draw attention to the fact that soil degradation and desertification are reaching alarming proportions and seriously endangering human survival. They call on states to cooperate and develop the tools to conserve soils. Key declarations relevant to soil include the 1972 *Stockholm Declaration on the Human Environment*, the 1981 FAO World Soil Charter, the 1982 *World Charter for Nature*, the 1982 *Nairobi Declaration*, the 1992 *Rio Declaration on Environment and Development*, and the 2002 *Johannesburg Declaration on Sustainable Development*. Also of relevance is the Programme for the Development and Periodic Review of Environmental Law for the First Decade of the Twenty-First Century, known as the Montevideo Programme; this program includes provisions to improve the conservation, rehabilitation, and sustainable use of soils.^[5]

International Conventions, Covenants, Treaties, and Agreements

Many multilateral agreements include provisions that could be used to promote sustainable use of soil, but the provisions are generally tangential to the needs of soil as such. Key global instruments relevant to soil include the 1992 *Convention on Biological Diversity*, the 1992 *United Nations Framework Convention on Climate Change*, the 1997 *Kyoto Protocol*, and the 1994 *United Nations Convention to Combat Desertification*. Relevant regional instruments include the 1968 *African Convention on the Conservation of Nature and Natural Resources* (Revised July 2003), the 1985 *ASEAN Agreement on the Conservation of Nature and Natural Resources*, the 1986 *Convention for the Protection of the Natural Resources and Environment of the South Pacific Region*, the 1986 *European Community Council Directive*, the 1995 *Convention Concerning the Protection of the European Alps*, and the 1998 *Protocol for the Implementation of the Alpine Convention of 1991 in the Area of Soil Protection*.^[6]

NATIONAL SOIL LAW

Legislation has been used for some years in many countries to control soil degradation problems and to manage

soil. A worldwide examination of national legal and institutional frameworks indicates that most countries approach the management of soil in a fragmented manner. The term “soil law” also covers those situations where comprehensive provisions for soil protection and management have been integrated in legislation that protects other aspects of the environment, such as forests, water, biodiversity, and desertification. In general, soil law thus provides for farm planning, implementation of soil erosion control measures, establishing community groups, planning catchment schemes, and compliance and enforcement. Some jurisdictions, such as the United Kingdom, have multiple soil legislation mechanisms that cover a broad range of functions including soil planning, access to sensitive land types, organic farming practices, nitrate sensitive areas, and soil restoration. On the other hand, federally organized countries often have a system where each state or province has its own soil legislation and supportive legal mechanisms. Hybrid situations also exist, such as in the People’s Republic of China, which has enacted the *Water and Soil Conservation Law 1991* and the *Desertification Law 2002* at a national level, but causes them to be implemented through a comprehensive provincial system of law and regulations.

There is a wide variety of types of legal mechanisms used to protect and manage soil, including acts, decrees, resolutions, ordinances, codes, regulations, circulars, decisions, orders, and bylaws. Whereas these are generally appropriate, many need to be applied in more inventive ways to effectively manage the soil in an ecosystem context.^[3]

EFFECTIVENESS OF SOIL LAW

The effectiveness of international and national soil law is generally dependent on two matters: first, the capacity of a legal and institutional framework to manage soil—which is measured by the ability of a legislative and institutional system to achieve sustainable use of soil—and second, by the number and type of essential legal and institutional elements present in a soil statute in a format that enables soil degradation issues to be identified. These need to be backed by the legal, administrative, and technical capability in the particular instrument as a basis of some form of effective action. Capacity is also represented in the form of legal rights, the type of legal mechanisms, and importantly, the number and comprehensiveness of the essential elements and their functional capabilities. Legal and institutional “elements” for soil are the basic, essential components of a legal and institutional system. An individual law can include a number of legal mechanisms in a well thought-out structure that gives an organization the power it needs, through its executive and administrative structure, to address soil degradation. It is also possible that the necessary elements may be distributed among a number of individual laws within a comprehensive national legal and institutional system.^[7]

Most key soil management issues are multifactorial (i.e., many include a sociological, a legal, and a scientific component), so it is obvious that generally more than one piece of environmental legislation (along with detailed regulations) and many types of legal and institutional elements will be needed to effectively manage soil degradation issues.^[7] Legal and institutional elements can be used to assist in the evaluation of an existing law or legal instrument to determine its capacity to meet certain prescribed standards of performance for the sustainable use of soil. They can also be used to guide the reform of an existing soil law or to develop new legislation for the sustainable use of soil. The manner and degree in which an “essential element” is applied will vary according to the particular type of legal mechanism concerned and its expected role in a particular jurisdiction. For example, an international legal instrument may include a provision for dispute resolution, but the actual implementation of this provision between states might not rely on, or be influenced by, the existence of similar provisions within a law of either of the disputing states.^[7]

IUCN COMMISSION ON ENVIRONMENTAL LAW

The Commission on Environmental Law of International Union for Conservation of Nature (The World Conservation Union) has carried out extensive investigation into the options for a new international instrument focusing on soil. The commission has also identified a variety of ways available for states to approach the task of a detailed legal and institutional analysis and the design of appropriate legal and institutional systems that provides for the effective management of soil. Arising from this work, in which the authors have been centrally involved, two principal strategies can be considered for the development of legal and institutional arrangements for soil. These are as follows:

A non-regulatory strategy that is characterized by elements for education, participatory approaches, soil management, and incentive schemes

A regulatory approach that is characterized by statutory soil use plans that prescribe legal limits and targets of soil and land use, issue of licenses or permits to control soil use, and the use of restraining orders and prosecution for failure to follow prescribed standards of sustainable soil use.

These strategies can be approached on a short-term time frame for implementation or a longer term time frame,

which involves substantial reform of existing laws, policies, and institutional and sectoral change.^[7]

CONCLUSION

Soil law has been neglected at the international level and, in many of the world's regions, at the domestic level. However, the growing recognition of soil degradation as a major international environmental issue in the context of the conservation of biological diversity is gradually being addressed, and this is starting to change attitudes toward the benefits of improved international and national legal and institutions for soil.^[8] Soil bodies represent complex terrestrial ecosystems. They require careful management of their ecological characteristics through the medium of soil law at a national and international level. This approach is essential for the long-term sustainable use of soil and to meet the food production requirements of the expanding human population of the world as well as to meet the needs of all flora and fauna that depend on the soil for sustenance.

Abstract

Soil management exists at the intersection between natural systems and human systems. Property rights are an important element in the transactions between man and the land. Soil health relies on property rights regimes that encourage the owner of the property right (individual or communal) to achieve their private goals, in ways that are sustainable. In this entry, the linkages between property, society, and soil health and some myths about property rights are explored.

INTRODUCTION

This entry considers the nature of property rights as institutional arrangements for the exploitation of natural resources and the role that they can play in conservation. It looks at myths about property and dangers that these pose for policy. This entry begins by considering property as a key element underpinning the transactions between social and natural systems.

A transaction between man and soil involves a decision, triggering a flow of either information or material things. Thus, a soil scientist may interpret “signals” from the soil, while the farmer may decide to plant and irrigate, and then interpret the results of these decisions in deducing what to do next. Behind these transactions and the elements that are shaping them are institutions made up of rules and organizations. Examples of rules include zoning for land use, environmental controls, water allocation rules, rules applied by financiers or communities, and rules agreed between neighbors.^[1] Property is a fundamental institutional arrangement in both capitalist and non-capitalist economies (though the nature and management of property vary with jurisdiction). It comprises both the legal rules and the institutional arrangements of ownership. Owners (those with a property right) are motivated to pursue gain, using those resources in an economically productive way.

PROPERTY

Legal property consists of rights to things, which society will enforce on behalf of the citizen. “What society

will enforce” is not universal or fixed. It changes with culture and society over space and time. This is contrary to the common perception of property law as an unchanging structure. Rigidity may be true for short term and for most purposes, but it is not true across time and space. Carbon trading, biodiversity markets, and weather futures require property rights unknown to a prior generation.

From Roman law, there is a legal distinction made between things unowned (*res nullius*), owned by the state, and owned by individuals (*res privatus*) or by groups of individuals (*res communales*). Under the British “common law” heritage, property is a theoretical construct with the flexibility to create new rights to meet new social or economic requirements. Property rights can be envisaged as a “bundle of rights” capable of division and adjustment by agreement (the term bundle of rights was first cited in the 1888 *Treatise on the Law of Eminent Domain in the United States* by John Lewis, cited in Goldstein^[2]). This bundle includes the right to possess, the right to alienate, the right to exploit, the right to control (and thereby exclude), and the right to the “fruits” of the thing, among others. These hallmark rights are core attributes of property. As a minimum, they need to be stable, ascertainable, and capable of assumption by third parties, for the law to give the imprimatur of property.

Because of the link between wealth, political freedom, and increased economic productivity (for those with property or a lack of wealth and social injustice for those without), property is a frequent element in political conflicts. In some societies such as the United States, a history of conflict led to an entrenchment of

private property as a civil right.^[3] In others, struggles to overcome poverty and injustice led to an elevation of other social interests over ownership. Property rights are a tool of social policy.^[4]

The linkages between soil health and property rights are many. Ownership of private land carries the right to exploit that resource to achieve private outcomes that may be harmful. The owner may place a premium on exploitation to achieve short-term gain rather than the long-term public good of soil health. An example is depletion of soil through excessive chemical addition to secure short-term profits. Conversely, ownership also provides an incentive to maintain soil health for further exploitation and to protect its productive capacity.

MARKETS

The trend in developed economies has been to extend the private property rights to things that were previously not the subject of ownership. They include rights of extraction (water), rights to contaminate (sulfur dioxide emissions), rights to conserve (wildlife), and rights to use (grazing). The ownership interests span time-limited interests (licenses, permits, or rights to profits) through to permanent allodial-like ownership. The divisibility of property rights allows new or recast rights to be added to the overall bundle as “green wood” rights.^[2] These can facilitate environmentally positive outcomes but equally can enable further exploitation of the resource.

Along with property rights, markets are often created. This is done by legally excluding valued use by non-owners. This then means that non-owners have to buy interests from the owners of the newly created rights. Examples include water markets, carbon markets (where emitters in effect buy sequestered carbon), pollution offsets, and “bio-banking” (where those who wish to reduce biodiversity in one area are obliged to purchase protection or rehabilitation in another).^[5]

Increasing ecological concerns are reflected in the trend to restrict the exercise of traditional property rights by regulation. Where this constraint is very strong, it can be argued that the property right has been removed or fundamentally changed. This may be sufficient in some jurisdictions to trigger rights to compensation for “taking.”^[6] Regulatory control for soil conservation has long been identified by prescient commentators as necessary to reduce loss of soil organic matter, to properly regulate consumption, and to increase the level of soil organic matter over time.^[7]

As with the use of property rights for social and economic purposes, regulation can also result in undesirable effects. Economic models often suggest that tradable entitlements using property are more efficient than regulation to achieve environmental and social policy goals. In practice (given social and economic complexity

and varying institutional performance), the results are more ambiguous than the models. The empirical evidence is that both regulation and market approaches share the potential to fail or cause perverse effects, unless carefully tailored and well implemented by effective institutions.

MYTHS

Myths and misunderstandings exist about what is required to use property rights successfully. Property is cultural. A property instrument that works in one society can fail in another. The most useful example of ignoring cultural effects is the belief that common property systems fail as methods of resource management in developed economies. This is referred to as the “Tragedy of the Commons.”^[8] There is sufficient truth in the Tragedy of the Commons myth to pay attention to the risks of common property, but sufficient empirical evidence to suggest that tragedy is not preordained. Even in developed economies, common property can be pivotal to economic activity (as the conventional public company with ownership allocated by shares demonstrates). It is often overlooked that one of Hardin’s prescriptions to avoid the tragedy was the use of less than fee simple property rights in threatened resources to encourage their protection and sustainable use.^[9]

A property myth that can mislead policymakers is the concept of unattenuated property rights. Many commentators suggest that a private market cannot efficiently work unless the owners of property have very secure rights. While it is understandable that private owners will want secure rights, the empirical evidence is that, provided there is a sufficient perceived opportunity for gain, entrepreneurs will innovate and exploit even given property right uncertainties. The historical evidence of the flowering of private enterprise at times when the State had absolute freedom to take is sufficient to prove this point. The modern example of trading in options where exercise is uncertain serves to reinforce it. The danger in property right mythologies is that they may lead to naive policy formulation that will not achieve optimal results.

CONCLUSION

Property rights are a powerful tool, but like all tools they depend on being used well, in the right situation. Property rights can adjust interests and harness self-interest to social goals. However, their effect is conditioned by other institutional arrangements and the context into which they are introduced. Good design of a property regime is not a matter of adopting some category of right and then expecting that this alone will ensure desirable outcomes. Sophisticated design and efficient institutions are critical. Even then it is necessary to manage

implementation with an eye to potential failures. The most difficult concern is social justice for a private market works, by facilitating the movement of resources from the less economically competent to those most efficient at the use of resources. Ensuring that this occurs in a way that is not unjust is a difficult challenge that few societies have achieved.

Leaching and Illuviation

Lynn E. Moody

Earth and Soil Sciences Department, California Polytechnic State University,
San Luis Obispo, California, U.S.A.

Abstract

The dynamic system of soils includes various types of translocations, involving movements of materials in aqueous solution or suspension, from one part of the solum (leaching or eluviation) into another part of the solum (illuviation). During translocation, organic and inorganic materials may be deposited into the upper part of the soil profile or produced or liberated in the upper part of the profile by physical, chemical, and biological weathering. The dominant translocation process in a soil profile depends partially on the form of the materials (inorganic or organic; solutes or particles). At a given stage of soil development, one process may be dominant or several may operate simultaneously or sequentially. In all cases, percolating water is the mechanism of translocation, and the rates and intensities of translocation processes are controlled by the factors that regulate water percolation: climate, topography, and tortuosity of soil pores. The last is usually quantified and expressed as hydraulic conductivity.

LEACHING

Leaching is the translocation of solutes. Some authorities specify that leaching is the removal of solutes entirely out of the solum, representing a loss of materials from the soil profile,^[1] but according to many experts, leaching includes the translocation of solutes within the solum.^[2] Solute arise mainly by chemical weathering and include ions, complex ions, and ion pairs.

Mineral weatherability depends on several factors of mineral and soil chemistry. It also depends on particle size (smaller → more soluble). If chemical bonds between ions in a mineral are ionic in character, then the ions readily detach from the mineral surface and enter solution,^[3] as in the congruent dissolution of halite into $\text{Na}^+(\text{aq})$ and $\text{Cl}^-(\text{aq})$. Chemical bonds with some covalent character, as well as ionic character, are less easily disrupted. Because they generally require a strong polarizer such as H^+ , dissolution proceeds less readily,^[3] as in the incongruent weathering of feldspar: $2\text{KAlSi}_3\text{O}_8 + 11\text{H}_2\text{O} + 2\text{CO}_2 \rightarrow 2\text{K}^+(\text{aq}) + \text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4 + 2\text{HCO}_3^-(\text{aq}) + 4\text{H}_4\text{SiO}_4(\text{aq})$. In this reaction, particulate kaolinite, as well as solutes, is produced.

The relative weatherability of the common silicates was tabulated by Goldich.^[4] Olivine, pyroxenes, and calcium (Ca) plagioclases are most weatherable, and quartz is most resistant (Fig. 1). Of the common non-silicates, sodium (Na) salts (including sodium carbonates) and chlorides of Ca, magnesium, and potassium are soluble, sulfates less so, and carbonates are slowly soluble. The solubility of iron (Fe) and manganese (Mn) oxides depends on the oxidation state of the metals; reduction of Fe and Mn in saturated soils causes their oxides to dissolve. As minerals weather and

elements are leached away, the soil unit decreases in mass and volume.^[5]

When chemical conditions in the soil are suitable, solutes precipitate, usually deeper than the origin of the solutes. One or more of several conditions, including the following, may initiate precipitation of solutes. Desiccation, the removal of water by evaporation or sorption by roots, may cause precipitation of soluble salts, gypsum, carbonates, or silica (Si). Reduction in carbon dioxide partial pressure below the zone of maximum biological activity is an additional cause of pedogenic carbonate precipitation. Solubility of many minerals is partially dependent on pH; therefore, a change in soil pH may also cause precipitation. Oxidation of Mn and Fe causes the oxides and oxyhydroxides of these metals to precipitate. As materials precipitate in the soil, mass is added and the volume increases.^[5]

PODZOLIZATION

Podzolization is a specific term for such leaching and precipitation of Fe and aluminum (Al) chelates within the solum. Such leaching may occur in humid climates, acidic soil conditions, and characteristically under coniferous or mixed coniferous–deciduous forests. The types of soils formed by podzolization are Podzols, generally equivalent to Spodosols in the U.S. taxonomy. The morphological expression of podzolization is a Bs, Bh, or Bhs (spodic) horizon, where the h symbolizes humus and s denotes Al and Fe sesquioxides. Often, the spodic horizon is overlain by a highly leached E (eluvial) horizon. A spodic horizon may be cemented by enrichment in humus, Al, Fe, and Si,

Fig. 1 Goldich's mineral stability series in weathering of the common rock-forming silicate minerals is displayed. Minerals least resistant to chemical weathering are at the top; resistance to weathering increases downward. Quartz is most resistant.

Source: From Goldich.^[4]

in which case it is known as *ortstein*. A placic horizon is a thin, wavy, cemented layer enriched in humus and Fe or Fe and Mn that is often associated with Podzols.

Two models have been developed to describe the podzolization process. The first model, favored by most authorities, involves the translocation of Al and Fe as organometallic complexes.^[6] Fulvic acids, components of humus, are formed during the decomposition of acidic leaf litter, especially litter from conifers and ericaceous (heath) plants. Humification is complex and probably a combination of processes involving the breakdown of lignin and the synthesis of phenols and aromatics from carbohydrates and amino acids.^[7] Fulvic acids are water-soluble anions under acidic soil conditions and, thus, mobile with percolating water. They are rich in phenols and carboxyls; the juxtaposition of these functional groups enables the organic matter to chelate trivalent cations Al and Fe. The organometallic complexes are carried downward in the percolating water. In an aerated, acidic environment, the metal cation/organic anion ratio mainly controls the solubility of the organometallic complex. If the cation/anion ratio is low, the complexes are soluble and, thus, mobile; they become less soluble by increases in the cation/anion ratio.

Precipitation of the organometallic complexes may be initiated at depth in the solum because of an increased ratio of the chelated trivalent cation to the organic anion. This shift in the cation/anion ratio may be brought about by microbial decomposition of the fulvic acids or by saturation of the complexes by greater concentrations of Al and Fe released by weathering. As all available chelation sites are filled, the molecules lose polarity, become hydrophobic, and precipitate. Precipitation also may be initiated by desiccation, sorption of the complexes onto mineral surfaces, or flocculation in the presence of divalent cations. As the organic matter eventually decomposes, Al and Fe are released from complexation and are free to form oxyhydroxides or sesquioxides. With the addition of Si, Al can form imogolite and allophane.

The second model, contrasting model of Podzol formation, holds that the dominant translocation process is inorganic and that organic acids are involved mainly in weathering rather than in transport.^[8,9] Weathering of primary minerals by carbonic and organic acids at the soil surface releases Al, Fe, and Si. At pH < 5, hydroxyaluminum cations react with Si to form stable, mobile, inorganic "proto-imogolite" complexes. The complexes precipitate in deeper horizons as imogolite and allophane, by desiccation or reaction to higher pH. Evidence supporting this model consists of Podzols containing Al predominantly as imogolite, allophane, and proto-imogolite and Fe as oxides, with Al-fulvic acid chelates sorbed and precipitated on allophane surfaces.^[10]

These two models may not be exclusive. Early podzolization in some Greenland soils involved translocation of Al and Fe by inorganic processes, whereas later stages involved their transport in complexes with organic acids.^[11] However, most studies of Podzols favor the organic model,^[12,13] even in the early stages of podzolization.^[14]

ILLUVIATION OF CLAYS

As the finest particles in soils, clays (<2 mm diameter) are most susceptible to eluviation (removal) and illuviation (deposition). Fine clays (<0.2 mm), in particular, are small enough to be mobile in soil profiles. Larger particles, even silts and very fine sands, may be mobile in some soils, depending on the size and geometry of pores and velocity of percolating water.^[15] Clays originate in soils by physical reduction of particles to clay size, by chemical transformation or precipitation, or by introduction as wind-transported dust. Once clays are present, their translocation in a soil profile involves mobilization, removal and transport, and deposition in a lower part of the profile.

Clay particles must be detached from the greater soil mass to enter into aqueous suspension. *Slaking* is physical detachment, by swelling during wetting, dislodgment by the shear of water flow, raindrop impact, or wind shear. *Dispersion* is chemical detachment that can result from the introduction of waters with low electrolyte concentration, dominance of Na compared to divalent cations on the exchange complex, or high pH. Clay minerals differ in their mobility: of the phyllosilicates, smectites are most easily dispersed, and kaolinite and illite, less so.^[16] Once detached, particles are then free to move in percolating water.

Pore space in most soils consists of micropores and macropores. Macropores may be animal burrows, channels left by decayed roots, large interstitial pores between coarse fragments, or spaces between peds. Under saturated conditions or during infiltration of free water from the surface, percolating water carrying detached clays

Fig. 2 Argillans (arrows) filling cracks between coarse prisms. This view is looking down on exposed tops of the prisms.

flows preferentially and, with greater velocity, through macropores than through micropores of the soil matrix. Water in the large pores is drawn into drier and microporous fabric by matric suction. The micropores serve a filtering function, and clay particles coat the walls of the large pores and the faces of peds as clay coatings (known as argillans, clay films, clay skins, or clay linings; Figs. 2 and 3). Phyllosilicates assume a face-to-face configuration, with the c-crystallographic axis approximately perpendicular to the ped face or pore wall. The orientation of phyllosilicate particles gives the argillan a strong optical orientation. To the unaided eye, and at low magnification, the argillan appears shiny or waxy. At high magnification of petrographic microscopy, the argillan displays undulatory extinction as the microscope stage is rotated under crossed polarizers.

Pore walls that do not allow appreciable water absorption, such as between rock fragments and sand grains, also

Fig. 3 Microscopic view under plane polarized light of loamy fine sand, with argillans (arrows) filling interstitial pores between sand grains (S) and lining a large pore (P).

develop clay coatings by illuviation. Drying of clay suspensions following downward flow of suspensions draws in the water interface progressively closer to the grain surfaces and to contact points between grains. Clay particle deposition follows the pattern of drying, argillans are thicker at the contact points than away from them, and phyllosilicate particles orient with faces parallel and crystallographic axis perpendicular to the surface.^[17] Thus, clay coatings on grains, and as bridges between grains, have a strong optical orientation.

The depth to which the suspension percolates determines the depth at which the deposition of clay particles occurs. The wetting front, driven by a potential gradient, stops where and when gravitational, pressure, and matric forces acting on the water reach equilibrium. The retarded water evaporates or is sorbed by roots, and suspended particles are deposited at the depth of water percolation.^[18,19]

Soil scientists accept the strongly oriented argillan as evidence of clay illuviation. However, phyllosilicate clays, which are deposited by flocculation (upon encountering high electrolyte concentrations or in the presence of di- and trivalent cations), tend to assume edge-to-edge or edge-to-face configuration and may not develop strong optical orientation. Thus, their illuvial origin may be difficult to identify. Finally, after deposition, argillans may be modified or destroyed by shrink-swell or mixing of soil material by animal burrowing.

CONCLUSION

Because the processes of leaching and precipitation, podzolization, and illuviation are highly dependent on water movement into and through the soil, any activity or land use that interrupts water infiltration and percolation will disturb those processes. Physical disturbances of the soil, such as tilling, may mix soil materials in such a way that soil horizons will be disturbed, mixed, or effaced.

Liming and Lime Materials

Mark K. Conyers

New South Wales Department of Primary Industries, Wagga Wagga Agricultural Institute, Wagga Wagga, New South Wales, Australia

Abstract

“Liming” is the application of an alkaline compound of calcium (Ca) to soil. The main aim is to neutralize excessive acidity in the soil by reaction with the alkaline anion, and the secondary aim is to supply Ca. Liming is a major tool, along with tolerant plants, in the management of acidic soils.

ACIDITY

The quantity of acidity that is regarded as “excessive” varies with the soil and with the species and cultivar of plant. Direct hydrogen ion (H^+) toxicity is uncommon in mineral soils but can occur in peaty soils of low pH. A high concentration of H^+ also has an indirect effect on legume growth by inhibiting the symbiotic relationship between the host plant and rhizobia. In most mineral soils, low pH is associated with aluminum (Al) toxicity to plants. Plants vary in their tolerance to Al (e.g., medics are generally sensitive; tropical grasses are generally tolerant). In some soils, manganese (Mn) toxicity is also a limitation to plant growth. Plant tolerance to Al and to excessive Mn is independently inherited. Plant breeding for tolerance to Al and Mn toxicity is used as either an alternative to using limestone, where the cost of liming is uneconomic, or in conjunction with liming, where subsurface acidity or seasonal conditions limit the effectiveness of liming.^[1] The application of liming materials does not always overcome Mn toxicity, as it can occur at higher pH than Al toxicity and may be induced by hot, dry soil conditions or by waterlogging. On the other hand, too much alkali added to a soil can induce deficiencies of Mn and also of other trace elements such as iron, zinc, and boron. In view of the potential for imbalanced plant nutrition, what constitutes “excessive” soil acidity is best determined by trials on local soils with local species and cultivars.

Deficiencies of calcium (Ca) and magnesium (Mg) also occur in some acidic soils. Ca deficiency is more commonly found in tropical species such as the peanut. Ca is also of benefit to soil structure; it is mainly applied to soils with large proportions of sodium on the cation exchange capacity and also to non-cracking clay soils with a large proportion of Mg on exchange sites. Where soil structure is a concern, gypsum is normally the preferred source of Ca, sometimes in combination with fine limestone. Gypsum is not an alkaline salt and hence does not add alkalinity to a soil.

While most liming materials can overcome Al toxicity and Ca deficiency, the alleviation of Mg deficiency requires the application of a liming material with a significant component of Mg. This may be either dolomite or a Mg-rich limestone, commonly known as dolomitic limestone. There is in fact a continuum between pure limestone and pure dolomite. Magnesite may be used to provide Mg but is rarely used as a liming material per se.

LIMING MATERIALS

The application rates of liming materials are best expressed relative to a standard such as calcium carbonate ($CaCO_3$). To overcome an existing problem of excessive acidity as opposed to a prophylactic dressing, application rates range from as little as 1 tonne $CaCO_3$ per hectare on weakly buffered soils, growing Al- or Mn-tolerant plants, to 10 tonne $CaCO_3$ per hectare on strongly buffered soils supporting sensitive plants. Weakly buffered soils include sandy textured soils and tropical Oxisols, particularly with low concentrations of organic carbon (OC). Strongly buffered soils include acidified Mollisols and soils with high contents of clay or OC. In high lime requirement situations, the $CaCO_3$, or its chemical equivalent, need not be applied in a single dose. Higher application rates than outlined here may be required for the amelioration of acid sulfate soils; however, this requires a separate consideration from the present focus.

Some common lime materials are listed in [Table 1](#). Most agricultural lime is some form of $CaCO_3$. This is generally in the mineral form of calcite, which occurs in limestone, marble, marl, and aged coralline deposits. Crushed shells and formed coralline material may be in the aragonite form of $CaCO_3$. The aragonite form is more soluble than the calcite form. Dolomite has a harder crystalline form than either of the $CaCO_3$ forms and is generally less reactive in soils.^[2] It has to be crushed finer than limestone to react in a similar time frame, but if Mg is required the only alternative

Table 1 NV and Ca content of pure liming materials.

Substance	Formula	% NV ^a	% Ca ^a
Limestone	CaCO ₃	100	40
Dolomite	(Ca _{0.5} ·Mg _{0.5})CO ₃	109	22
Burnt lime	CaO	178	71
Hydrated or slaked lime	Ca(OH) ₂	135	54
Ca silicate	CaH ₂ SiO ₄	75	30
Magnesite	MgCO ₃	119	0

^aRounded to nearest whole percent.

to dolomite is to spread both crushed limestone and a separate source of Mg such as magnesite.

Industrial waste materials are also commonly used for liming. Precipitator dusts from clinker and cement manufacturing contain varying proportions of CaCO₃ and calcium oxide (CaO). The latter has an exothermic and caustic reaction with water and so should be handled with care.^[3] The risks increase as the proportion of oxide in the waste increases. Ca silicates from steel manufacturing can also be good liming materials.

Liming materials can be broadly grouped as follows:

Natural deposits—dolomite; calcite (limestone, coralline and earthy limestones, and marble); aragonite (fresh shell and coralline materials). Further refinement is available.^[4]

Manufactured forms—burnt lime; slaked or hydrated lime.

By-products—precipitator dusts (mixtures of carbonates, oxides, etc.); slags (usually Ca silicate wastes from steel production).

Incidental forms—where liming is not the principal function of the material: reactive rock phosphate, dicalcic phosphate, sewage ash, manures, and composts.

Fig. 1 The increase in limestone efficiency in raising soil pH with decrease in particle diameter.

Source: From Meyer & Volk,^[6] Beacher, Longnecker, et al.,^[7] and Scott, Conyers, et al.^[8]

The reactions, which neutralize acidity, other than for incidental liming materials, can be exemplified as follows:

In each case, 2 mol of acid are consumed per mole of liming compound. While the second reaction liberates the greenhouse gas carbon dioxide, as does the increase in OC mineralization that follows liming, in the longer term, the removal of the constraint of soil acidity increases plant root and top growth, and so net C fixation can be enhanced.

Purity and Fineness

The effectiveness of traditional liming materials such as limestone and dolomite depends on their purity and fineness. Clearly, the more pure the limestone or dolomite, the greater the quantity of acid that can be neutralized by each tonne of product. In more general terms, the ability of any type of liming material to neutralize acidity is termed neutralizing value (NV). It is a measure of the ability of a given mass of liming material to react with acidity, expressed relative to a standard such as CaO^[5] or CaCO₃. The latter is adopted here. For pure minerals and compounds, NV is easily calculated by the following calculation:

$$\text{NV} = \frac{\text{mole wt of CaCO}_3}{\text{mole wt of compound}} \quad (2)$$

For example, for CaO,

$$\text{NV} = 100/56 = 1.78 \quad (3)$$

Results for pure compounds are given in Table 1. For compounds of mixed or unknown composition, the NV is obtained by titration after the dissolution of liming material in excess acid. Details of the method can be obtained by reference to the latest edition of the Official Methods of Analysis of the Association of Official Analytical Chemists.

The fineness of a liming material is a more controversial issue, not because of differences in experimental results but because of differences in opinion about the cost of production of fine lime and the ease of spreading. Fig. 1 shows the results of three studies on the ability of calcitic limestone to raise soil pH as a function of particle size.^[6–8] The degree of agreement between these pot and field studies, conducted by different workers on different continents 50 years apart, is remarkable. In none of these studies was there an upper limit where fineness was of no further benefit in lifting pH. The concept of a “plateau” in particle-size effectiveness, referred to in some texts, is a subjective assessment of, firstly, the practical limitations of spreading fine limestone and, secondly, the cost of the liming material relative to its agricultural value.

Despite the clear demonstration of the value of fineness, there are two reasons why it is not necessarily helpful to define an “ideal” particle-size distribution for all calcitic liming materials. First, the agricultural context has to be considered. On the one hand, the need for finer limestone is most apparent for crops grown in regions of relatively low rainfall. On the other hand, for sandy soils receiving 2000 mm rainfall annually, it may be unnecessary or wasteful to have a high proportion of fines as there may be losses of the limestone from surface soil through mass flow. On the one hand, where cartage and spreading costs are a large proportion of the total cost of liming, it is more cost effective to cart and spread a product that is almost 100% effective. On the other hand, if the farm is near to a limestone quarry and if the farmer has his own lime spreader, then he may be able to regularly spread higher tonnages of relatively coarse limestone quite cheaply. On the one hand, a high ratio of lime cost to agricultural product value also means that limestone has to be used as cost effectively as possible. On the other hand, in an intensive horticulture, the cost of lime may be relatively minor and a higher application rate of coarser limestone may be as cost effective. Therefore, the agricultural context of the liming has to be considered.

Second, the lime crusher’s industrial perspective needs to be considered. If the limestone crushing plant services industries such as glass, plastics, and collieries, there is more chance that the plant will have a ball mill, enabling the manufacture of fine limestone. If the main focus of the plant is to produce agricultural limestone, it may not be reasonable to expect the milling of very fine products. The cost of producing a fine limestone simply for soil amelioration may diminish the cost competitiveness of the crushing plant. On the other hand, the milling of fine limestone may give a lime producer a strong advantage over the competition. Local circumstances need to be considered. The same principle holds for by-product liming materials; the introduction of a processing step such as milling may in some instances make the by-product uneconomic. However, without milling, a coarse slag may be nearly useless. Therefore, the ways in which local by-products are best used should be determined by field trials and economic analysis.

The purpose of quantitative models of efficiency for liming materials should not be to dictate terms to crushers and other producers but to enable consumers to assess the relative cost effectiveness of alternative products available to them. The concept of an “ideal” liming material is likely to vary with local circumstances.

CONCLUSION

Despite claims in some popular literature, limestone has no “cure all” properties; it is a part of the solution for the specific problem of excessive soil acidity. The best management practice (type of lime, fineness, rate of application, incorporation method, etc.) needs to be determined for each mix of agricultural and industrial circumstances.

Loess

Fred E. Rhoton

National Sedimentation Laboratory, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Oxford, Mississippi, U.S.A.

Helaine W. Markewich

U.S. Geological Survey (USGS), Atlanta, Georgia, U.S.A.

Abstract

Loess is a wind-blown silt that originates from outwash alluvium downstream of receding glaciers and from the surface of desert soils, covering approximately 10% of the earth's surface. Both the thickness and particle size of Loess decrease precipitously within a short distance from the source area. In addition to being highly fertile and productive, Loess and Loess-derived soils have an inherently low resistance to erosion by water and wind. Consequently, in the presence of adequate rainfall and/or windstorms, Loess becomes the most erosion-prone material on earth. Environmental problems resulting from Loess erosion include loss in productivity, air and water quality degradation, and coincident medical ailments resulting from particulate matter and chemicals/trace elements associated with the eroded material.

INTRODUCTION

For almost two centuries, the study of Loess and Loess-like deposits has provided controversy and consternation. In general, Loess is considered largely unstratified silt-sized dust/material that mantles the landscape in blanket-like deposits. Loess deposits are widely distributed, with the most extensive deposits occurring in the Central United States, eastern China, Northern Europe, and Argentina. Loess deposits are also recognized in Alaska, Siberia, and Canada.

Environmentally and culturally, Loess deposits are considered as both assets and detriments. Some of the most fertile, highly productive agricultural soils in the world are developed on Loess,^[1] which is inherently high in plant nutrients, available water-holding capacity, and porosity. Conversely, there are many problems associated with Loess due to its unfavorable physiochemical properties. Most unweathered Loess is devoid of cementing agents such as clay, iron (Fe) oxides, and organic matter. This lack of cementing agents results in unbound silt-sized particles that do not form erosion-resistant structural units, which in turn results in Loess and Loess-derived soils having very low resistance to water and/or wind erosion. Loess erosion results in significant local-to-regional degradation of soil, water, and air quality.

ORIGIN OF LOESS

Four major events have been suggested^[2] during the formation of a Loess deposit: formation of the silt-sized

material (20–60 μm), transportation, deposition, and post-depositional changes. One of the original arguments as to the origin of Loess deposits was whether they were alluvial or eolian.^[3] Since the early 1920s, Loess has been traditionally defined as wind-deposited silt, which in many cases is difficult-to-impossible to differentiate from Loess-like colluvium and/or alluvium. Making this distinction addresses the problems of how Loess material is made and how it is transported.

Much of the world's Loess material is “made” by glacial grinding, resulting in finely ground rock powder (flour) being deposited by glacial meltwater. Since the middle of the 20th century, a number of researchers showed that weathering processes in very cold alpine and desert environments can also produce significant amounts of Loess material.^[4–6] Small amounts of Loess material also form in warmer deserts, but the resulting Loess deposits generally are of local extent.^[7]

In a dry state, the silt-sized material associated with each process eventually becomes airborne and is transported by strong, generally prevailing, winds at distances determined by particle size.^[8] Wind action during the transport phase results in physical sorting and a deposit characterized by homogeneous particle sizes, primarily in the coarse-to-medium silt size range (20–50 μm , U.S. Department of Agriculture scale).

Origins of Loess deposits are explicitly linked to eolian processes that transport sediment from bare surfaces of glacial till, outwash alluvium, and desert soils. These represent the primary sources of fine sediment available for wind transport.^[9] Finely divided rock

Fig. 1 Typical topography of Loess deposits in the Lower Mississippi River Valley near Vicksburg, Mississippi.

powder (or flour) produced from glacial scour eventually is transported, sorted, and deposited by meltwater streams. The meltwater deposits are entrained by winds, sorted again, and redeposited along the edge of continental glaciers and adjacent to major meltwater river valleys. As a result of multiple sortings, Loess of glacial origins consists of finer particle sizes compared to Loess derived from desert origins, which may have undergone only one sorting event.^[10]

Silt-sized particles are most likely to be transported by winds blowing across source areas. The silt transport process is initiated by the saltation of sand grains moving across surfaces that dislodge and suspend silt grains to altitudes as high as 3 km and to downwind distances that exceed several hundred kilometers.^[9] A decrease in wind velocity initiates Loess deposition in amounts and particle sizes that are greatest to the source areas. As the downwind distance increases, the thickness of Loess deposits and particle size decrease proportionately. Once deposited, Loess appears as a

blanket draped over the landscape (Fig. 1), with the lower contact conforming to the Preloess topography.

LOESS DISTRIBUTION

Loess deposits are widely distributed on a global basis, covering approximately 10% of the total landmass (Fig. 2) primarily between latitudes 30° N and 50° N, the zone that generally corresponds to the southern extremities of glaciation in the northern hemisphere.^[10] The most extensive areas of Loess occur in Europe ($1.8 \times 10^6 \text{ km}^2$), the United States ($1.6 \times 10^6 \text{ km}^2$), Argentina ($7.2 \times 10^5 \text{ km}^2$), and China ($6.2 \times 10^5 \text{ km}^2$).^[9,11,12] The thickest Loess deposits are found in China, averaging about 150 m.^[13] By contrast, Loess thickness in the Central United States is 8–15 m, with maximum thickness of 20–35 m being recorded along eastern edges of major river valleys.^[9] Average Loess thickness adjacent to major rivers in Western and Eastern Europe is 5–10 m, with maxima

Fig. 2 Global distribution of major Loess deposits.

Source: <http://www.geog.ouc.bc.ca/physgeog/contents/11r.html>.

Fig. 3 Weathered Peoria Loess overlying a Paleosol in Carroll Co., Mississippi.

between 30 and 50 m.^[9] Argentinean Loess thickness ranges from 10 to 30 m over vast expanses and locally may exceed 100 m.^[11] Loess deposits in Alaska^[9] and Siberia^[14] range from < 10 to 60 m.

LOESS CHARACTERISTICS

Loess deposits appear to have a unique suite of characteristics regardless of location. These similarities can be attributed to the eolian processes responsible for Loess formation. Deposits are massive except for clay lenses and zones of carbonate and/or organic matter accumulations resulting from weathering and pedogenic activity. Where present, Paleosols (Fig. 3) mark periods of minimal or non-deposition. In a relatively unweathered state, Loess colors are predominately pale yellow to brown.^[15] As weathering reactions progress, relative Fe concentrations increase, and Loess colors will tend toward more brown or red hues.

Loess deposits, by virtue of their wind-blown origin, commonly possess an open structure with a pore space in the range of 50–60%. This high porosity value likely contributes to the instability of Loess in a wet state. Although remarkably stable in vertical cliffs (Fig. 4) when dry, upon wetting, Loess has a tendency to collapse. This is in large part due to the high percentage of pore space and the lack of cementing agents such as clay, Fe oxides, organic matter, or carbonates.

Characterization data for Loess deposits in the mid-continental United States, Central and Eastern Europe, China, and Argentina are very comparable relative to changes in particle size as a function of distance from source.^[16] The major factor then influencing the particle size composition of Loess deposits in different locales is proximity to the source. As the downwind distance of the source increases, both Loess thickness and particle size decrease dramatically in the first few kilometers and continue to decrease logarithmically for short

Fig. 4 Vertical slope in a Loess deposit near Vicksburg, Mississippi.

distances before reaching a minimum that remains constant regardless of distance from source.^[8]

Although Loess deposits may show uniformity of particle size at distance from source areas on a global basis, their chemical and mineralogical compositions are often dissimilar. In relatively unweathered Loess, this variability can be attributed to differences in the composition of parent materials in glaciated and non-glaciated source areas and the composition of strata incised by streams transporting the outwash; e.g., Loess deposits in the lower Mississippi River Valley were ultimately derived from granitic rocks in the Canadian Shield, whereas Argentinean Loess was derived from volcanic rocks (pyroclastic).^[12] The chemical composition of the two Loesses is similar to the extent that both are dominated by silica and aluminum, but the calcium and magnesium concentrations of the U.S. Loess are considerably greater and Fe concentrations are lower than those of the Loess from Argentina.^[17]

CULTURAL AND ENVIRONMENTAL ASPECTS OF LOESS

The importance of Loess to civilization for several millennia has been documented worldwide. Soils developed on the Loess Plateau, China, have been cultivated for 6000 years and are credited with allowing for the establishment of early Chinese culture.^[18] Loess soils had similar impacts in India and Mesopotamia. The early agricultural settlements in Europe were established in areas with Loess-derived soils.^[19] In the American Midwest, crop yields from loess-derived soils that dominate the region have been unrivaled for centuries.

In addition to the favorable aspects of Loess, there are several problems endemic to these regions. Soil/Loess loss to erosion by water can reach astronomical levels. Loess and Loess-derived soils have the distinction of being more susceptible to erosion than any other soil material. On a global basis, Loess regions sustain the greatest soil erosion losses. The northwest and midcontinent regions of the United States and the Pampas region of Argentina are excellent examples of Loess-blanketed areas with high erosion rates. The Loess Plateau of China undoubtedly has the most serious erosion problem in the world. The region is responsible for 90% of the estimated 1.6 billion tons of Loess received by the Yellow River on an annual basis.^[18,20] By comparison, the Mississippi River at Vicksburg, Mississippi, U.S.A., transports an annual average of 225 million tons of sediment, even though this region receives two to three times more rainfall than the Loess Plateau of China.

The effects of erosion are twofold: loss of productivity and degradation of the environment. In areas of extreme erosion, such as the Loess Plateau region, environmental damage related to sedimentation poses a greater problem.

The Yellow River carries between 10% and 40% of its weight as silt-derived sediment, or approximately 10 times the content of other rivers of the world.^[21] This load is equivalent to 10 million cubic meters of sediment annually. Much of this sediment is caught in reservoirs, decreasing their storage capacity by about 10% per year.^[22] The consequences are a reduction in hydroelectric output, water available for irrigation, flood control potential, and navigable waterways.

In summary, Loess is a wind-blown silt that originates from outwash alluvium downstream of receding glaciers and from the surface of desert soils, covering approximately 10% of the earth's surface. The most extensive deposits, in terms of area, exist in Europe, the United States, Argentina, and China, in this order. The thickest deposits are found on the leeward side of major stream valleys. Both the thickness and particle size of Loess decrease precipitously within a short distance from the source area. In addition to being highly fertile and productive, Loess and Loess-derived soils have an inherently low resistance to erosion by water and wind. Consequently, in the presence of adequate rainfall and/or windstorms, Loess becomes the most erosion-prone material on earth. Environmental problems resulting from Loess erosion include loss in productivity, air and water quality degradation, and coincident medical ailments resulting from particulate matter and chemicals/trace elements associated with the eroded material.

Abstract

The Loess Plateau area, the most widely distributed region of the Loess on the earth, is mostly located in the middle reaches of the Yellow River, covering 8 latitudes (33–41°N) and 14 longitudes (100–114°E) with an area of 624,000 km². Current landform of the Loess Plateau formed due to neotectonism, rising–falling movement, fault activities on a large scale, and Loess deposition process. The Loess Plateau area located at a transitional zone from monsoon climate of the eastern China to semiarid and arid climate in the northwestern China, the Loess Plateau experiences a prominent continental monsoon climate. The Loess Plateau can be bioclimatically divided into forest, forest steppe, and steppe zones from the southeast to the northwest, while soil is both determined by climate condition and human activities. As a consequence of special landform and human activities, the Loess Plateau is one of the most severely eroded areas in the world. However, a set of soil and water conservation projects has been implemented on the Loess Plateau and obtains great ecological and economic benefits.

INTRODUCTION

The Loess Plateau area is located in the upper and middle reaches of the Yellow River (the Huanghe River). It is bordered by the Yinsan Mountain in the north, extending southward to the Qinling Mountain, and by the Riyue Mountain in the west, stretching eastward to the Taihang Mountain (Fig. 1). The Loess Plateau area covers 8 latitudes (33–41°N) and 14 longitudes (100–114°E) with an area of 624,000 km². The Loess Plateau area and its dusty soil cover most areas of Shanxi, Shaanxi, and Gansu provinces and cover parts of Qinghai and Henan provinces, Ningxia, and Inner Mongolia Autonomous Regions. The Loess deposits with depth of 50 to 200 m thick. Loess is the name for the silty soil that has been deposited by wind storms on the plateau over the ages. Loess is a highly erosion prone soil that is susceptible to the erosional forces of wind and water.

The Loess Plateau area is the most widely distributed region of the Loess on the earth, where the thickest Loess–Paleosol sequence has been developed. The Loess Plateau area, with an altitude of 1000–1600 m characterized by various geomorphologic units, includes high plains with deep-cutting gullies (Fig. 2), hilly gully (Fig. 3), rock mountains, wide valley plain, and sand-depositing land (sandy land). Its surface is covered by averagely 100 m thickness of Loess–Paleosol layers. The Loess was geologically transported from the

northwestern Gobi desert by winds and accumulated on the Loess Plateau since the beginning of the quaternary (about 2.5 million years before).^[1] The alternations of Loess and Paleosols, in conjunction with their enclosed faunas and distinctive mineralogies, have been widely interpreted as reflecting quaternary glacial/interglacial episodes.^[2]

As one of the most severe soil erosion regions in the world, over 60% of the land in the Loess Plateau area has been subjected to soil erosion, with an average soil loss of 2000–2500 t km⁻² yr⁻¹.^[3] For example, the amount of soil erosion from some watersheds in the Huangfuchuan basin reached 59,700 t km⁻² yr⁻¹, and maximum sediment concentration in the river water was measured as high as 1640 kg m⁻³.^[4] Soil erosion has seriously depleted land resources and degraded the eco-environment in the Loess Plateau, which directly affects local socio-economic sustainable development. Furthermore, soil loss on the Loess Plateau area is the major source of sediment load in the lower reaches of the Yellow River. The sediment delivery in the Yellow River is increased after it flows through the Loess Plateau area. Mean annual suspended sediment concentration in the Yellow River measured at the Shanxian Observatory, is 37.6 kg m⁻³, and a sediment load of 1.64 billion tons per year (before 1980)^[5] was observed at the Sanmen Gorge, Henan Province (Table 1), which is 9 to 21 times greater than that of the most major rivers in the world. Therefore, soil erosion control is a critical issue in the Yellow River basin.

Fig. 1 Location of the Loess Plateau area.

Of the 1.6 billion tons of annual sediment delivery, 0.4 billion tons was deposited in the downstream river channel at a sedimentation rate of about 10 cm yr^{-1} before 1980. Thus, lower reaches of the Yellow River's riverbed

is 4–10 m higher than the adjacent land. Since the 1990s, sediment delivery has greatly decreased and thereafter, sediment delivery of the Yellow River is about 0.3 billion tons per year.

FORMATION OF THE LOESS PLATEAU AND LOESS DEPOSITION

The Loess Plateau at the end of the Cretaceous period was in peneplain stage. At the beginning of Eocene epoch, the peneplain started to fold and arch, and was completely broken up at the end of the Oligocene epoch. Thereafter, because of neotectonism, rising–falling movement, and fault activities on a large scale, the basic landforms such as mountains and basins were formed. The landforms before Loess deposition on the Loess Plateau may be roughly grouped into three types:

1. In the east, the Wutai, Lüliang, and Zhongtiao old upland in Shanxi Province, being repeatedly under the process of orogenic movement, denudation, deposition, and the effects of magma explosion in the north had formed the two parallel folded mountain series of the Taihang and Lüliang Mountains and a series of basins. Here, Loess covered piedmonts, basins, and valleys below the altitude of 1500 m. The thickness of Loess deposition is generally less than 30 m, except in the Taiyuan Basin and wide valleys where Loess deposit is thicker.

2. In the middle, the high plain and the rolling flat mound were formed through the successive cutting and denudation of the Ordos platforms. Although the platform has risen gradually and evenly, the gentle folds within the platform were formed under the influence of Yanshan Movement, and the grabens and faults were formed at the edge of the platform due to the influence of Himalayan Orogeny. The high plain formed after the vast areas were covered with thick Loess deposit in the typical Loess Plateau, with an area of about 280,000 km², an altitude of 1000–14,000 m, and Loess layer of about 100 m thickness. The grabens and valley basins are at an altitude of 400–500 m only.
3. In the west, Longxi basin between the Liupan Mountain and the Qilian Mountain has frequently been subjected to the influence of denudation, accumulation rising and falling since the Nanshan movement and has formed a series of long mounds, pointed mountains, low gentle hills, and piedmont plains. The Loess could deposit as high as 2000 m or more above the sea level.

Table 1 Erosion episodes of valley erosion.

Erosion/ deposition cycle	Oxygen isotope of deep sea	Age (×1000 years)	Erosion episodes
Erosion	Interval glacial epoch	10	Present
Deposition	Glacial epoch	29	
Erosion	Interval glacial epoch	61	The third stage
Deposition	Glacial epoch	75	
Erosion	Interval glacial epoch	128	The second stage
Deposition	Glacial epoch	185	
Erosion	Interval glacial epoch	242	The first stage

During deposition of Loess in different periods, the neotectonic rising movement was still going on. Hence, Loess deposition was often accompanied by erosion. Loess in this region has been mostly transported by wind for about 2.5 million years. Natural conditions of this region and the original region of the Loess have gone through many periodical changes over a very long time. Accordingly, Loess deposition also had periodical intermittence, and during the intermittent periods, Paleosol profiles reflecting the initial landscape and biometeorology formed.

In the beginning of quaternary period, the Loess Plateau had Loess deposition on a large scale; Wucheng Loess, Lishi Loess, Malan Loess, and Loess of the Holocene epoch had deposited continuously. In the meantime, erosion process

occurred. Loess–Paleosol profile shows that four erosion periods were experienced during the Loess deposition (Table 1).

CLIMATE CONDITION AND WATER RESOURCE

The Loess Plateau is located at a transitional zone from monsoon climate of the eastern China to semiarid and arid climate in the northwestern China. Continental monsoon climate is very prominent. Annual average temperature is 4.3°C in the northwest and 14.3°C in the southeast. Temperature in January (the coldest month) is from −14°C to −8°C in the northwest and −4°C to 0°C in the southeast, and temperature in July (the warmest month) is 20°C to 24°C in the northwest and 24°C to 28°C in the southeast. Annual precipitation ranges from 200 mm in the northwest to 700 mm in the southeast, and more than 50% of the precipitation occurs in June, July, August, and September. Dominant rainfall pattern is rainstorm, wherein the rainfall from single rainstorm accounts for 15–25% of the annual precipitation while rainfall from a large storm accounts for 40–50% of the annual precipitation.^[6]

Moreover, there is much sunshine in the Loess Plateau area. Annual sunshine time is 2100–3100 hr. The annual solar radiation is about 5–6.3 billion J per m². More than and equal to 0°C accumulated temperature is 3200–3900°C, and the period without frost is 150–200 days.^[6]

Annual average runoff volume from the Yellow River basin is about 56.3 billion m³, and the ground water volume is about 26.3 billion m³.

VEGETATION AND SOIL

The Loess Plateau can be bioclimatically divided into forest, forest steppe, and steppe zones from the southeast to the northwest. Paleo-pollen analysis shows that there had been luxurious forest cover during warm–wet periods in the quaternary. However, vegetation clearance started about 3000 years ago for cultivation, resulting in vegetation cover becoming very sparse. According to investigation on the residual vegetation in field edges, gully slopes, and rock mountain areas, there are more than 500 species of grasses, 250 species of trees, and 3000 species of herbs and bushes. The dominant species are *Pinus*, *Quercus*, *Ulmus*, *Artemisia*, *Bothriochloa ischaemum*, *Stipa bungeana*, *Lespideza dahurica*, and *Cleistogenes chinensis*.^[7]

According to the natural bioclimatic condition, there would be brown soil or cinnamon (Heilutu) within the forest zone in the south, chemozem or chestnuts in forest steppe and steppe zone in the middle, and desert soil or brown calcium soil in desert-steppe zone in the north. However, for several thousands of years, human activities have caused extensive destruction of the natural

vegetation cover and resulted in a profound modification of the original soils. Chinese soil scientists called it agricultural Loess soil and subdivided it into three groups: Lutu soil, Zhong Heilutu soil (heavy black loam), and Qin Heilutu soil (light black loam) in Chinese soil classification system.^[8] They are comparable to Ustalfs or Udalfs in the U.S. Department of Agriculture system or Luvisols in the Food and Agriculture Organization system.^[1]

The Loess is characterized by low soil organic matter content (0.2–1%), weak alkaline (pH value ranges 7.2–7.8) reaction with carbonate specks, and coarse to medium granular structure with biopores and vertical joints. Its profile is typically characterized by an alternation of silty or sandy Loess (yellow Loess layer) with more clay-rich Paleosols (brown–red layer). The pedogenesis process in the Loess–Paleosol sequence is rather unique. A Loess layer formed under the condition of dust accumulation rate outweighs the pedogenesis rate, and during the period of Paleosol formation, the dust accumulation was not stopped but was only slower than the pedogenesis.^[2] The Loess layers, which represent strong deposition process, have been affected by pedogenetic process in different degrees. Their soil types are mainly steppe or forest-steppe soils. In addition, there are aggregates, pores of earthworm and plants, and certain tree composition in pollen assemblage. It shows that the Loess layer had been subjected to pedogenetic process of steppe or forest-steppe undersemiarid climate.

GEOLOGY AND LANDFORM

The Loess Plateau is one of the most active areas of tectonic movement in China. Right from the quaternary period, there have been large areas of crustal uplift of about 150–200 m. With crustal uplift, valleys are formed and water concentrates into rivers in the valleys. The energy of water in the rivers causes increased soil erosion in the valleys. In addition, the Loess Plateau has become an area with frequent earthquakes due to tectonic movements. A harmful earthquake not only causes gravitational erosion but also destroys the structure of the Loess, leading to large areas of collapse and sliding. Moreover, the composition of Loess generated by rock and soil-forming processes results in substantial amounts of fine sandy loam and silt loam with strong tensile and stress joints so that collapse of the soil may happen only after 1–2 minutes in water. This Loess characteristic leads to high erodibility including channel and cave formation.

The main geomorphic landforms on the Loess Plateau are Yuan (a large flat surface) (Fig. 2A), ridge (“liang” in Chinese) (Fig. 3A), hill (“mao” in Chinese) (Fig. 3B) and various gullies. The degree of slope is also an important factor affecting soil erosion in Loess Plateau. Soil erosion becomes more intense as the slope increases.

SOIL EROSION ON THE LOESS PLATEAU

Vegetation removal and agricultural development started about 3000 years ago on the Loess Plateau area. Consequently, soil erosion became increasingly severe. The Loess Plateau is one of the most severely eroded areas in the world. Land area affected by soil erosion is 430,000 km², accounting for 81.1% of the total area of the Loess Plateau, of which severe soil erosion is 280,000 km², accounting for 52.8% of the total area. Every year, about 0.01–2 cm of topsoil is washed away.

Due to different climatic conditions, geographical features, and human activities, the regional distribution of soil erosion in the Loess Plateau is obvious. Generally speaking, there are three erosion areas, i.e., the wind erosion area, the wind–water erosion criss-cross area, and the water erosion area (Fig. 4). Among the three erosion regions, the water erosion area (Area III in Fig. 4) is the most important region because population is mainly concentrated in this region, and it is also a main sediment source of the Yellow River. Depending on the distinctly different geomorphology and erosion patterns, the water erosion area is divided into two subregions, i.e., the hilly gully subregion (Fig. 3) and the high Loess plain, with deep-cutting gullies, subregion (Fig. 2). Gully erosion occupies more than 60% of total soil erosion in a watershed in the hilly gully subregion and more than 80% in the high Loess plain with deep-cutting gullies. According to a gully survey, there are about 660,000 gullies, which are more than 500 m in length. In the Loess Plateau, the area with the highest gully density is near the Yellow River in the Shanxi and Shaanxi provinces, which became the main coarse sediment producing area in

Fig. 5 Vertical distribution of water erosion patterns along hill-slope in the Loess Plateau.

the middle reaches of the Yellow River;^[9] for example, sediment from the North Shaanxi province occupies about 50% of total sediment delivery in the Yellow River.

Water erosion patterns along the slope shows a vertical distribution. From upslope to downslope, dominant erosion process follows the sequence of splash–sheet erosion–rill erosion–ephemeral gully erosion–gully erosion. Fig. 5 is a typical example of vertical distribution of water erosion patterns in the hilly gully region of the Loess Plateau. With the change of erosion patterns along the slope length, erosion intensity gradually increases. Generally speaking, sheet erosion, rill erosion, and ephemeral gully erosion frequently distribute in the cropland; all these inducing a decline of soil quality and reduction in crop productivity, and consequently affecting vegetation restoration.

Wind erosion is a secondly important environmental problem in the Loess Plateau, and is one of the main dust sources of sand storms in China. The wind erosion area

Fig. 4 Regional distribution of soil erosion of the Loess Plateau.

Fig. 6 Desert landscape of the Mu Us Sandy Land in the Loess Plateau (A and B).

mainly covers part of the Ordos Plateau (Area I in Fig. 4), which is bordered by the Great Wall in the south, extending northward to the Yinshan Mountain, and by the Helan Mountain in the west, stretching eastward to Linger–Dongsheng–Yulin line. It includes the Maowusu Sandy Land (Mu Us Sandy Land), Kubuqi Desert (Hobq Desert), Hedong Sandy Land, and Hetao Plain. The total area of wind erosion is about 180,000 km², accounting for 25.08% of the Loess Plateau.^[10,11] The domestic terrain is high plains, and the desert (sandy land) landscape is obvious (Fig. 6). Average annual precipitation is almost below 300 mm, annual evaporation is 2500–3000 mm, and the coefficient of humidity is 0.23–0.1 or less. The drought environmental and geographical attributes lead to the shrub species becoming dominant and make the vegetation transmitting from steppe to desert steppe.^[12,13] However, as the wind erosion area on the Loess Plateau mainly consisted of the desert, sandy land, and the Gobi, the erosion hazard is not obvious and has not gained much attention.

Another specific erosion area related to wind erosion which contributed to high soil erosion, is the wind–water erosion criss-cross area on the Loess Plateau. The wind–water erosion criss-cross area is a corridor between the water erosion area and the wind erosion area, extending mainly between 35°25′–40°38′ N and 103°00′–113°53′ E (Area II in Fig. 4). This area is notorious for dramatic climate changes, with frequent occurrences of natural disasters, such as flood, rain gush, drought, and sandstorm. Annual precipitation is 250–400 mm, and the uneven inter-annual precipitation distribution rate ranged between 2 to 7 times that of the normal year.^[11] Therefore, soil erosion occurs all year round, in which water erosion is dominant in

summer and autumn, and wind erosion mainly occurs in winter and spring. Due to the complex environmental and geographical attributes, about 216,000 km² out of the total 178,000 km² of the wind–water erosion criss-cross area is severe erosion region with the average annual erosion intensity more than 10,000 t km⁻²; and the extremely severe erosion center of the Loess Plateau, whose annual erosion intensity can reach 150,000 to 250,000 t km⁻², is located in the contiguous area of Shanxi, Shaanxi Provinces, and Inner Mongolia Autonomous Region.^[14,15]

EROSION CONTROL ON THE LOESS PLATEAU

Since 1950, a set of soil and water conservation projects have been implemented on the Loess Plateau, comprising construction of large reservoir at the main stream and branches of the Yellow River, backbone dam and check dams in gullies, and integrated management of small watershed. Implementing these projects has brought great benefits for both ecology and economy. Especially in 1999, Grain for Green Project (GGP) was issued as one of the government policies for Chinese ecological restoration, which means steep cropland was converted to permanent vegetation cover with the government giving some compensation to local farmers, including grain, cash, and seedling fee. After more than 10 years of GGP implementation, local landscape has obviously changed (Fig. 7) and local farmers' livelihoods have greatly improved. Owing to implementation of several soil and water conservation projects, obvious stepwise decrease in sediment load has occurred in the Yellow River, and thus as a result, ecological

Fig. 7 Local landscape change caused by GGP on the Loess Plateau.

security is greatly improved. Both on-site and off-site positive impacts on ecology and economy of erosion control are remarkable.

Abstract

Agriculture is a vulnerable sector to the climate changes, and Brazil is one of the major contributor of greenhouse gases (GHGs). Thus, the implementation of effective strategies for both mitigation and adaptation to climate change for agriculture is very important for development and also to infer sustainability to the Brazilian agricultural sector. The “low-carbon agriculture” aims to develop processes and technologies that promote mitigation of GHG emissions in agriculture and enable the adaptation of the agricultural sector to climate change. Thus, in Brazilian semiarid region, developing technologies with no-tillage systems concomitant with green manure and agrosilvopastoral systems are adapted to climatic conditions to infer sustainability in the livestock and agricultural sectors.

INTRODUCTION

The greenhouse gas (GHG) emissions have their dynamic emission to the atmosphere related to agricultural production processes, changes in land use, the burning of fossil fuels, and industrial activities. In a global level, changes in land use added to the agricultural production processes contributed 22% of carbon dioxide (CO₂) emissions, 43% of methane (CH₄) emissions, and 85% of nitrous oxide (N₂O) emissions. In Brazil, historically, this sector contributed 75% of CO₂ emissions, 91% of CH₄ emissions, and 94% of N₂O emissions, considerably higher in relation to global averages.^[1] Thus, conservation technologies, based on low-carbon (C) agriculture, are fundamental to mitigate the impact of land use change and climate change on GHG emissions.

Studies directed to determining the impact of land use change and climate changes in C stock are sporadic in the Brazilian semiarid region, mainly because of large variability and mosaic distribution of the soils and vegetation.^[2] This question assumes greater importance in the face of

climate change scenarios for the Brazilian semiarid region in which extreme events would negatively impact agricultural production.^[3–4] Thus, this entry presents the main concerns related to the land use change and agriculture in Brazilian semiarid region, and the low-C agriculture technologies adapted to climate conditions that will imply sustainability to regional production system.

LAND USE CHANGE IN THE BRAZILIAN SEMIARID

The Brazilian semiarid region, with 969,589 km², has 28 million people, including urban areas, representing 11% of the country, and 1.6 million agricultural establishments, with 95% classified as family farms. Caatinga is the most representative Brazilian semiarid biome, with an approximate area of 844,453 km²,^[5] which is formed mainly by low trees and shrubs, many of which have thorns, microphyll and xerophytic characteristics, and herbaceous with great importance because of its foraging,

medicinal and apicultural value.^[6] However, the change of land use with the use of woody plants for energy production together with the use conversion aimed at agricultural production is responsible for the removal of 46.38% of caatinga vegetation.^[7] Livestock is the main land use followed by rainfed agriculture and irrigated agriculture, changing the soil C stock. In this sense, Sampaio and Costa^[8] estimated that the average soil C stocks in caatinga areas, native pasture, planted pasture, and crops are 100, 90, 80, and 70 Mg ha⁻¹, respectively.

TECHNOLOGIES TO MITIGATE THE LAND USE CHANGE AND CLIMATE CHANGE IMPACTS

No-till farming, green manures adoption, agroforestry systems, silvopastoral systems, and organic farming are technologies used in semiarid region to increase the soil organic C content, consequently reducing the GHG emissions.^[9–11] They are fundamental to consolidate a low-C agriculture adapted to the soil and climatic conditions of the Brazilian semiarid.

No-Till System and Green Manure

In the Brazilian agricultural soils, no-till contributes to both increased soil microbial biomass and C sequestration, with increments from 5.2 to 8.5 Mg C ha⁻¹, superior to soil under conventional tillage.^[12] However, there are difficulties to implement that practice in the Brazilian semiarid region due to climatic limitations and the traditional requirement of crop residues to livestock feed.^[13] Conversely, the priority of the soil conservation in Brazilian semiarid region with the use of cover crops and its residues allows the increase of water infiltration and retention, the increase of organic matter content, the decrease of soil temperature oscillations and evaporation, and, subsequently, the decrease of the salinization process. In this sense, many studies have focused on no-tillage system development for corn crops,^[14,15] melon,^[16] cowpea,^[17] and watermelon.^[18] All the proposed crop systems consist of rotation, succession, or intercropping, with emphasis on the green manure use. Among the technologies studied and implanted with no-till system in Brazilian semiarid region

stands out the use of plant cocktails. Thus, the studies of irrigated areas in Brazilian semiarid region have been developed using plant cocktail as green manure in mango crop (since 2005) and melon crop (*Cucumis melo* L.; since 2011), as technology for low-C agriculture.

Studies have already been developed with species cultivated as plant cocktail, covering different proportions of grasses, legumes, and oilseeds to evaluate the best composition in the culture under study.^[19] Grasses generally contributed to relatively large amounts of biomass and characterized by a high C/nitrogen (N) ratio that increases the persistence of soil cover over time.^[20] On the contrary, the leguminous species, which fix atmospheric N, have high levels of N in plant biomass, and their residues generally have low C/N ratio with relatively fast decomposition that promotes a small soil cover.^[21] The Brazilian semiarid region has a potential to add large amounts of C and nutrients in the soil of agricultural systems in a short period by means of the green manure crops (Table 1). The plant cocktail biomass increases the rate of adding C that may be stored in the soil system over time.

There is a lack of studies on no-till system impact and green manure on C dynamics in the Brazilian semiarid soil, both taking into account the topsoil along the profile. In Brazil, the studies carried out throughout the territory estimated that soil C stocks are 39, 52, 72, and 105 Pg in 0.0–0.3, 0.0–0.5, 0.0–1.0, and 0.0–2.0 m layers, respectively.^[22] The distribution of C on profile decreases significantly with the soil use, initially in surface and after in subsurface,^[23] demonstrating that there are significant differences between the surface C and C in depth.^[24]

The roots contribute twice as much to the soil organic C compared to plant aerial part due to a higher proportion of lignified tissue.^[25] The production of biomass and the root cycling, especially the thin ones, influence the amount and dynamics of C in soil. The root cycling is regulated by soil moisture and temperature and microbial activity due to their biochemical characteristic^[26] or associated with plant hormonal and physiological reactions. In arboreal stratum, due to the high renewal rate over the tree life cycle, there is a high rate of adding C to the root system.^[27] Consequently, in addition to the aerial biomass contribution of the green manure is also important to quantify the production of root

Table 1 Production of dry matter and nutrient accumulation in the aerial part of plant cocktail and spontaneous vegetation (Petrolina, Embrapa semiarid region, 2013).

Note: L, legumes; NL, no legumes.

biomass and the nutrient accumulation by the roots along the soil profile. It was verified that green manure cultivated in the Brazilian semiarid region added quantity of biomass ($5.0\text{--}5.6\text{ Mg ha}^{-1}$) and nutrient [N: $70.1\text{--}80.4$; phosphorus (P): $4.2\text{--}5.3$; potassium (K): $39.9\text{--}40.0$; calcium (Ca) $39.8\text{--}47.7$; magnesium (Mg): $5.8\text{--}7.3$; and sulfur (S): $6.3\text{--}6.8$] along the upper soil profile when compared with the spontaneous vegetation (biomass: 1.5 Mg ha^{-1} and N: 38.6 ; P: 2.0 ; C: 10.9 ; Ca: 17.7 ; Mg: 2.8 ; and S: 3.3). These observations do not include plant exudates and mucigels released by the root system during the development of the green manure. Thus, the use of plant cocktails as green manure in both mango crop and melon crop, even for a short period of time, increased the content of soil organic matter, initially occurring in the surface and subsurface layers. It was also observed that the highest C/N ratio influences the behavior of the humic fractions, indicating the formation of humus with less fulvatic character.^[28]

Understanding the dynamics of organic matter and accurately estimating C stocks in surface and subsurface are important to the development of technologies and sustainable agricultural systems and involve long-term studies. Lima^[29] evaluated the melon C footprint produced in Brazilian semiarid region, comparing the following production systems: conventional system used by most producers in the region and the conservationist system, in development and experimental scale with three-year cultivation, using no-tillage with green manure via plant cocktail. The conservationist system uses plant cocktail (composition: 75% legume species and 25% of no legumes species) as green manure without incorporation in soil. The C footprint results for a ton of melon produced and transported to the consumer market (State of São Paulo, about 2000 km) were $821\text{ kg CO}_2\text{eq}$ in conventional system and about $639\text{ kg CO}_2\text{eq}$ in conservationist system. The conventional system demands larger amounts of synthetic fertilizers, resulting in direct N_2O emissions and indirect NH_4 and NO_3^{2-} emissions that affect the melon C footprint, whereas conservationist system has lower contribution due to lower loss C, considering the amount of C returned to the soil by green manure biomass used.

Agroforestry System

The agroforestry system is a sustainable practice of natural resource management that combines forest species, agricultural crops, and/or livestock in the same exploitation area, simultaneous or in temporal sequence. This technology aims to ensure the production stability and diversity, increase productivity, improve soil fertility, and increase the supply of a good-quality forage.^[30] Besides, it reduces GHG emissions and increases the C stock in the soil and plant system.^[31]

The agrosilvopastoral system is the predominant agroforestry system in Brazilian semiarid region, combining crops, forest species, and animals in the same area. There is also the silvopastoral system with the introduction of

animals in areas with permanent and commercial tree species or with the introduction or maintenance of the tree component (native or exotic) in cultivated pastures and adapted to the region.^[32] Studies have shown that the preservation of natural trees during the cutting of caatinga trees or cultivation of native or introduced species may contribute to the preservation or restoration of soil fertility in agricultural or pasture areas in northeast semiarid region of Brazil. Sacramento et al.^[11] evaluated the changes in soil C stocks in the layer of $0\text{--}40\text{ cm}$, after 13 years of experiment installed in a typical Orthic Luvisols. They observed that silvopastoral agroforestry farming systems (97.59 Mg ha^{-1}) and agrosilvopastoral (71.64 Mg ha^{-1}) and traditional (with clearing of vegetation, burning, and cultivation during 2 to 3 years; 68.16 Mg ha^{-1}) systems had lower C stocks compared to the remaining caatinga vegetation (134.65 Mg ha^{-1}); however, the agroforestry systems outperformed the traditional system. But, some studies have shown that measurements of changes in some soil variables in agroforestry systems, such as total organic C, are imperceptible in less than 10 years.^[33]

Drumond^[34] highlighted that the main arboreal species with multiple potential use for agroforestry systems in the Brazilian semiarid region are as follows: *Leucaena* (*Leucaena leucocephala*), *Gliricidia* (*Gliricidia sepium*), Mesquite (*Prosopis juliflora*), Sabiá (*Mimosa caesalpiniiifolia*), and Eucalyptus (*Eucalyptus* sp.). These species have forestry development in areas dependent on rain with an average annual rainfall ranging from 500 to 700 mm.

Among the agrosilvopastoral models, the following stand out: 1) pastures cultivated with grasses: Buffel (*Cenchrus ciliaris*), Aridus grass (*Cynodon dactylum* var *aridus*), and Urochloa (*Urochloa moçambisensis*); 2) *Leucaena* protein banks (*Leucaena leucocephala*) grown in rows ($4.0 \times 1.0\text{ m}$) and intercropped with maize and/or beans; 3) *Gliricidia* protein banks (*Gliricidia sepium*) grown in rows ($4.0 \times 1.0\text{ m}$) and intercropped with maize; 4) cactus areas planted with the giant varieties (*Opuntia ficusindica*) and round varieties (*Opuntia stricta*), in a dense system, spacing $1.0 \times 0.25\text{ m}$ and $1.0 \times 0.5\text{ m}$, respectively, and in single-row system ($3.0 \times 0.25\text{ m}$) intercropped with *Gliricidia* (*Gliricidia sepium*), on lines and corn in between rows; 5) reforested areas with Sabiá (*Caesalpinia echinata*) established in spacing of $10.0 \times 3.0\text{ m}$; and 6) live fences with forage gliricidia.^[35] Among all systems, we highlight the importance of using leguminous species for biological N fixation.

The planting in alleys is also a technique used in Brazilian semiarid region to improve the quality of soil. It consists of plant trees in rows properly spaced between them, where among the lines are cultivated crops at the beginning of the rainy season. The main objective of this system is to increase the organic matter content, nutrient cycling, and addition of N in by green manure.^[36]

The main leguminous species used as alley farming are as follows: *Crotalaria* (*Crotalaria juncea*), Jack Bean

(*Canavalia ensiformis*), Black mucuna (*Stylobium aterrimum*), Guandu (*Cajanus cajan*), Leucaena (*Leucaena leucocephala*), Gliricidia (*Gliricidia sepium*), Sabia (*Mimosa caesalpinifolia* Benth), and Canafistula (*Peltophorum dubium*). The choice of these species will depend largely on weather conditions, soil types, and culture characteristics.^[37]

Gliricidia sepium, e.g., is a legume largely used in alleys farming due to good development conditions under water stress and high capacity of biomass production.^[38] Studies by Marin et al.^[38] evaluated the corn production and chemical composition and soil characteristics modifications with the use of *Gliricidia* in alley farming system in the semiarid region. They observed that the use of *G. sepium* did not alter the levels of total organic matter but significantly increased the light organic matter content, available P, and extractable K in soil.

Oliveira et al.^[39] evaluated the carbon management index (CMI), calculated from the C stock index and lability index,^[40] among the conventional agricultural systems and agroforestry systems in the semiarid region of Ceará, Brazil. They observed that the CMI showed the highest values for the agrosilvopastoral system (120–200%) compared to the silvopastoral (0–60%) and traditional (100–160%) systems. Therefore, according to the authors, agroforestry systems are effective for improving soil quality, increasing C stock, and promoting sustainability in these environments.

There are few studies involving the agroforestry systems impact on C stocks in soil and plant system, and also there are no systematic studies to assess the impact that integrates scenarios of global climate change in areas or long-term experiments in Brazilian semiarid region.

CONCLUSION

Agriculture and livestock are very important activities in the semiarid economy, characterized by caatinga biome. However, the extractive livestock, monoculture, excessive soil preparation, and lack of soil cover, promoted by land use changes, contribute to soil erosion, decomposition and mineralization, salinization, and/or sodification, decreasing the C stock in soil. Predicted impacts on climate change scenarios may potentialize the C stock reduction. Thus, the technologies and farming systems, such as no-tillage system associated with green manure and the agroforestry systems, are alternatives that can reduce GHG emissions, increase C sequestration, and mitigate the impact of climate change in the Brazilian semiarid region.

Abstract

The Eastern Himalayan region of India, also called the North Eastern Region (NER), comprises of eight states, namely, Arunachal Pradesh, Assam, Manipur, Meghalaya, Mizoram, Nagaland, Sikkim, and Tripura. The NER of India has geographical area of 26.3 million hectares and population of 45 million. Almost 85% of soils in this region are moderate to strongly acidic. About 47.5% land is prone to degradation by soil erosion, acidity, etc. Nutrient mining by extractive agriculture is the major reason for depletion of soil fertility. Decline in soil organic matter because of residue burning, excessive tillage, soil erosion, etc. along with the depletion of soil biological quality is the major concern. With the efficient management of available natural resources and need-based application of fertilizer and manure, soil health can be improved and sustained. Agroforestry, microwatershed-based integrated farming system, integrated nutrient management, conservation tillage, and residue management are among the options for sustaining soil health and agricultural productivity.

INTRODUCTION

The Himalayas represents the youngest but complex mountain system on the earth, which is still evolving and is recognized as 1 of the 34 global biodiversity hot spots. India's Eastern Himalayan region constitutes about 52% of total Himalayas [total of 52.42 million hectare (Mha)] and consists of eight states (Arunachal Pradesh, Assam, Manipur, Meghalaya, Mizoram, Nagaland, Sikkim, and Tripura) and Darjeeling hills of West Bengal. Located at the tri-junction of Indo-Chinese, Indo-Malayan, and Palaearctic biogeographic realms, India's Eastern Himalayan region has diverse hilly terrain with wide-ranging altitude. It shares the borders with China, Myanmar, Nepal, Bangladesh, and Bhutan. The temporal and spatial variations caused by diversity in geological orogeny have

resulted into a marked difference in climate and physiography and consequently in distribution pattern of biotic elements, including the domesticated ones. The Eastern Himalayan region, also called the North Eastern Region (NER), lies between 22°05' and 29°30' N latitudes and 87°55' and 97°24' E longitudes. The region represents three provinces (East Himalayas, Brahmaputra Valley, and North East Hills) and covers about 7.7% of the total geographic area of India.

Despite rich endowment of agroclimatic and geographical diversity, the NER has lagged behind in economic development. Nonetheless, there is an ample potential for development with abundance of natural resources. Soils in the valleys are rich in soil organic matter (SOM) but are mostly degraded. The SOM content is low to medium in arable lands on steep slopes because

of accelerated soil erosion. Around 56% of the cultivated area of the NER is under low altitude (valley or lowland), 33% under mid-altitude (flat upland), and the rest under high altitude (upland terrace). Traditionally, farmers in both upland terrace and valleys practice monocropping under rainfed agriculture, where rice (*Oryza sativa*) is the major crop occupying more than 80% of the cultivated area followed by maize (*Zea mays*). The cropping intensity of the NER is 130%.

The “slash and burn” agriculture (shifting cultivation or *Jhum*) is practiced on about 0.88 Mha. Deforestation and biomass burning in *Jhum* aggravate soil erosion and ecosystem degradation. *Bun* cultivation (raised beds of 0.15–0.30 m height and 0.75–1 m width with almost equal width under sunken area made along the slopes) is a modification of shifting cultivation and is mostly followed in the Meghalaya plateau. In the *bun* cultivation, biomass is burnt under the soil, and the land is abandoned after two or 3 years. This practice aggravates soil erosion and degradation. Annual soil erosion on steep slopes (44–53%) under shifting cultivation can be as much as 40.9 Mg/ha along with attendant losses (in kg/ha) of 702.9 of soil organic carbon (SOC), 63.5 of phosphorus (P) and 5.9 of potassium (K).^[1] Soil erosion, during the 1st and 2nd years, on the abandoned land has been estimated at 147, 170, and 30 Mg/ha, respectively.^[1] Steep slopes, cultivated along the slope, with negligible nutrient replacement and high rainfall are among the major causes of land degradation in the NER.^[2]

Maintaining and enhancing soil quality are crucial to sustaining agricultural productivity and environment quality. Indiscriminate use of intensive agriculture has adversely impacted soil and environment over the past decades. Biological methods of soil and water conservation, especially grass or vegetation cover, are suitable for hilly ecosystems and are cost-effective.^[2] Soil health management in the fragile hill ecosystems of the NER should be based on recycling of available plant residues, agroforestry, conservation agriculture, integrated nutrient management (INM), microwatershed-based integrated farming system (IFS) and permanent pasture grasses on sloping lands, and intensive IFS in valleys. The objective of this entry is to describe the status of soil fertility, explain different types of soil degradation, and outline some management options considering the availability of natural resources to sustain soil health and productivity in the NER.

Land Use and Agroclimatic Conditions

About 54% of the geographical area of the region is under forest—reserve, protected, and unclassed forest under the forest department. The land is mostly owned by communities and allotted to villagers for *Jhum* and other uses by the village headman or the land council. The states like Meghalaya and Tripura have no intact

forest. Forests in Mizoram (71.7%) and Nagaland (53.3%) are relatively core forest. Sikkim, Manipur, and Tripura have considerable area of forests which is threatened by severe fragmentation.^[3]

The net and gross cultivated area in the NER is about 4 and 5.7 Mha, respectively. The state of Assam has the maximum cultivated area followed by that in Nagaland and Meghalaya. Cropping intensity is the highest in the state of Tripura (184%) and the lowest in Mizoram (106%). The share of total cultivated area under food grain is the highest in Manipur (78.7%) followed by that in Nagaland and Arunachal Pradesh.

The NER has eight distinct agroclimatic zones starting from subtropical to temperate to alpine. Each state can be divided into agro-ecozones for agricultural planning and development. Rice is the main crop, and tropical and temperate fruits are also commonly grown. In Assam, Manipur, and Tripura, double-cropping of rice is practiced in plains, and fish farming is common in valleys. Tea (*Camellia sinensis*) husbandry is common in hills of Assam and Tripura. In low altitudes of Assam, Tripura, Manipur, and Meghalaya, rice, oilseeds, and vegetables are major crops. Rice, maize, ginger (*Zingiber officinale*), turmeric (*Curcuma longa*), and citrus (*Citrus* spp.) are important crops in hills. Maize and cardamom (*Elettaria cardamomum*) are important crops of Sikkim, which is the only organic state in India. In Tripura, there are three agro-ecoregions where double-cropping of rice is prevalent in plains. Pineapple (*Ananas comosus*), areca nut (*Areca catechu*), and vegetables are other important crops.

Soil Fertility and SOC Status

Most soils of the NER are rich in SOC and nitrogen (N) content, except those under shifting cultivation but are low to medium in P and medium to high in K. Soils of the humid subtropical regions (e.g., Tripura, Assam, and other foothills) are deficient in SOC and K. More than 85% of soils are acidic and have mild to severe acidity attributable to the leaching of basic cations due to heavy rainfall. P fixation is a problem in the soils, and substantial part of the P from applied phosphatic fertilizer gets immediately fixed and unavailable. Soils of the region are broadly classified under five orders, namely Inceptisols, Entisols, Alfisols, Ultisols, and Mollisols.^[4]

In Arunachal Pradesh, SOC concentration ranges from 14 g/kg in Dirang [1475–1775 m above mean sea level (AMSL)] to as high as 59 g/kg in Tawang (2700–2775 m AMSL). The SOC concentrations in other high altitude areas (1725–2300 m AMSL) like Bomdila (52.8 g/kg), Jerigaon (38.9 g/kg), Bomdir (34.5 g/kg), and Jung (48.7 g/kg) are also very high. In Manipur, SOC concentration ranges from 1–34 g/kg in Bishnupur valley to 5.1–36.6 g/kg in Imphal valley. Conversely, in the hill districts of Manipur such as Chandel (14.4–49.1 g/kg), Senapati (18.3–27.7 g/kg), Ukhrul (14.4–51.0 g/kg), Churachandpur

(15.2–26.8 g/kg), and Tamenglong (18.4–31.2 g/kg), the SOC concentration is very high. In Meghalaya, the SOC concentration is very high and ranges from 5.2 to 43.0 g/kg in East Khasi Hill and from 5.2 to 31.3 g/kg in West Khasi Hill districts. About 13% of soils in the valleys and 5.5% in the high altitude (>1700 m MSL) are low in SOC in Meghalaya. The soils of Mizoram are low to medium in SOC (4.2–13.4 g/kg) concentration. In Sikkim, the SOC concentration is high in most of the soils ranging from 23.5 to 44.5 g/kg. In high altitude areas of Sikkim (>1200 m AMSL), the SOC concentration is relatively higher in places like Gangtok (44.5 g/kg), Nagi (40.5 g/kg), Namthang (38.2 g/kg), and Turung (36.0 g/kg). However, SOC concentration is low in low altitude areas (<600 m MSL) of Sikkim like Singtam (23.5 g/kg), Rangpo (24.6 g/kg), Miming (29.2 g/kg), Majitar (26.0 g/kg), and Central Pendam (31.5 g/kg).^[4,5]

Under shifting cultivation, land is cleared off the existing vegetation, allowing the felled biomass to dry and finally burning the biomass in the month of March/April. Burning of aboveground biomass increases pH and cations and decreases carbon (C) and N contents in surface soils. The SOC content decreases after burning because of oxidative loss of carbon dioxide (CO₂). Soil loss to the tune of 40.9 Mg/ha and corresponding nutrient loss of 703 kg SOC, 63.5 kg P/ha, and 6 kg K/ha have been reported from shifting cultivation on steep slopes of 44–53%. Annual loss of topsoil, N, P, and K to the extent of 88,346, 10,669, 372, and 6051 Gg from the region had been reported, respectively.^[4]

SOC under Various Land Use Systems

Agricultural soils have large potential for SOC stock and sequestration and can be managed to reduce atmospheric concentration of CO₂. The SOC stock of different land uses including long-term experimental fields of Lembucherra, Tripura (<100 m AMSL); Umiam, Meghalaya (950–1000 m AMSL); and Tadong, Sikkim (>1500 m AMSL) was estimated at the following two depths: 0–15 and 15–30 cm. The objective was to recommend best soil management practices for SOC sequestration of different altitudes.

Lembucherra, Tripura (Low Altitude)

Soil sampling was done to analyze bulk density and SOC concentrations to estimate SOC stock from existing long-term land uses (>10 years) except for jatropha (*Jatropha curcas*) block that was 5 years old. In the studied soils of different land use systems of Lembucherra, Tripura, the SOC concentrations ranged from 8.6 to 16.4 g/kg at 0–15 cm and from 7.4 to 15.2 g/kg at 15–30 cm layers (Fig. 1). Among all the land uses, SOC stock was the maximum under bamboo (*Bambusa* spp.) plantations followed by that in *Tephrosia purpurea* alley cropping (AC) and duck-based farming

Fig. 1 SOC stock under different land uses in Lembucherra, Tripura.

system [FS (duck)]. Soils under mango (*Mangifera indica*) and arecanut had the lowest SOC stock.^[5]

Umiam, Meghalaya (Mid-Altitude)

At mid-altitude of Meghalaya, land uses comprising conventional tillage (CT), no-till (NT), recommended dose of fertilizer (RFD), organic farming (OF), *in situ* residue retention (IRR) in rice, maize, and pine (*Pinus kesiya*) forest (dominant forest), *Jhum*, and IFS [upper slope (US), middle slope (MS), and lower slope (LS) of hills] involving crop-livestock fodder on terrace risers were evaluated for SOC stocks. The SOC concentrations ranged from 16.4 to 34.7 g/kg in the 0–15 cm and 15.5 to 33.5 g/kg in the 15–30 cm layers (Fig. 2). Among all the land uses, SOC stock was recorded to the maximum under IRR in rice (10 years) in lowland followed by that in rice under OF. Pine forest had the lowest SOC stock among all the land uses. IFS involving crop-livestock (agropastoral) components had higher SOC stock in surface layer at US, MS, and LS than that under *Jhum* fields. Thus, IRR in lowland rice and the adaptation of IFS approaches are favorable for building soil fertility especially the SOC stocks.^[5]

Tadong, Sikkim (High Altitude)

In some soils of different land use systems of Tadong, Sikkim, the SOC concentrations vary from 17.6 to 29.2 g/kg in the 0–15 cm and 13.5 to 24.5 g/kg in the 15–30 cm layers (Fig. 3). Among all the land uses, SOC stock was the maximum in *Alnus nepalensis* system + cardamom (>20 years) and sal tree (*Shorea robusta*) + cardamom (>20 years) in the surface and subsurface layers, whereas the minimum SOC stock was recorded in soils under orange (*Citrus reticulata*) plantation (>15 years) in both the layers.

Impact of agroforestry, perennial forage crops, crop residue recycling and conservation agriculture^[6] on

Fig. 2 SOC stock under different land uses in Umiam, Meghalaya.

improving soil health and C sequestration has been reported under the NER.

Some Approaches for Soil Health Management

Integrated farming system

The alternative farming systems (eight IFS models) to shifting cultivation were developed by Indian Council of Agricultural Research, Research Complex for North Eastern Hill Region, Umiam, in 1983. Soil physicochemical properties were assessed after 20 years. The maximum accumulation of exchangeable Ca^{2+} was observed under cropping system and exchangeable K under agri-horti-silvi-pastoral system.^[7] There was a substantial buildup of available N in soils under all eight systems. The rise in available P in agricultural livestock-based system could be due to heavy and continuous dressing of cow dung litter

for a long period. Available K increased in all systems except that in the livestock-based farming system. The overall fertility buildup followed the trend of agriculture > agri-horti-silvi-pastoral > livestock-based farming system. The improvement in overall soil fertility due to various farming systems over shifting cultivation-based land use has been reported.^[8]

Integrated nutrient management

The use of N, P, and K fertilizer in the NER is only 13.4%, 11.1%, and 11.1%, respectively, of the crop removal, indicating a perpetual depletion and low productivity. In most cases, only N fertilizer is applied and P and K are neglected. In case of Manipur, the ratio of N/P/K application is 76.9:7.5:1, respectively. Integrated use of chemical fertilizers of 60 kg N/ha along with 5 Mg/ha farmyard manure (FYM) with the seed inoculation of *Azotobacter* can enhance rice yield, nutrient uptake, and N buildup in soils.^[8] Similarly, the application of single super phosphate with *Rhizobium* inoculation in black gram produced 69.1% increase in nodulation over control in acidic soils of Tripura.

Agroforestry systems (AFSs)

In hill ecosystems, AFSs play an important role in sustainability, resource conservation, and food security. Multistoried AFSs/home gardens are the classic example of agroforestry. Agri-horticulture, agri-silviculture, agri-horti-silvi-pasture, agri-pisciculture, and multitier systems are some of the important AFSs in the NER. Tree species (e.g., *A. nepalensis* and *P. kesiya*) have favorable effects on soil physical properties, particularly on soil bulk density, moisture content, and mean weight diameter of soil

Fig. 3 SOC stock under different land uses in Lembucherra, Tripura.

aggregates. About 33%, 50%, and 76% increase in soil available N, P, and K content, respectively, has been observed under *A. nepalensis* as compared to control. *A. nepalensis* and *Michelia oblonga* considerably favored the accumulation of SOC and available nutrients compared to other tree species under mid hill condition of Meghalaya.^[9]

Conservation agriculture

The retention of crop residues on the soil surface in combination with NT initiates processes that lead to improved soil quality and overall enhancement of resource-use efficiency. Higher SOC and total N contents under NT and residue retention in rice–pea (*Pisum sativum*),^[6] rice–lentil (*Lens culinaris*),^[10] maize–rapeseed (*Brassica campestris* var. toria),^[5] and maize–French bean (*Phaseolus vulgaris*)^[11] have been reported from the diverse ecosystems of the NER. Increase in SOC and soil nutrient status due to residue management under groundnut (*Arachis hypogaea*)–rapeseed system is also reported.^[12]

Organic farming

The fertilizer consumption is less than 12 kg/ha (excluding Manipur and Tripura) in the NER. The total potential for nutrient supply through crop residues in the region has been estimated as 9.86, 2.12, and 35.5 Mg of N, P, and K, respectively, thus creating on an average 2.46 kg N, 0.53 kg P₂O₅, and 8.87 K₂O/ha. Thus, a good quantity of potash can be added through crop residues.^[4] Growing leguminous shrubs such as *Crotalaria juncea* and *Tephrosia purpurea* around the farm fences can produce 5–6 Mg/ha green leaf manure containing 2.4–2.7% N, 0.3–0.6% P, and 0.8–2.0% K. It is an added advantage that every family maintains some cattle, and thus, the NER has about 13 million cattle population. A 5-year study indicated that the application of recommended dose of N through FYM or FYM + vermicompost is equally effective as organic amendment and their continuous application improved soil health and crop productivity.^[13] Organic production of rice, pea, lentil, carrot (*Daucus carota*), French bean, tomato (*Solanum lycopersicum*), potato (*Solanum tuberosum*), and okra (*Abelmoschus esculentus*) can sustain soil health and productivity in the NER.^[11]

Liming

Acid soils occupy nearly 85% of geographical area in the NER. Nearly 65% of the soils of the region are extremely acidic (below 5.5). Crops are affected by aluminum and iron toxicity, deficiency, and low base saturation. The furrow application of lime 250–500 kg/ha of high quality uniform grades/sizes at furrows every year can optimize the yields of crops in acid soils of the NER. The use of acid tolerant varieties and the application of organic manure also improve the productivity of such soils. The optimum

yield can be obtained by applying liming materials at 0.25 LR (lime requirement) or 1–1.25 equivalent soil exchangeable aluminum.^[14]

Micronutrient management

Acid soils are also characterized by the deficiency of micronutrients, particularly of boron (B) and zinc (Zn). The deficiency of B is commonly observed in light-textured acidic soils receiving high precipitation, which cover about 35% of the NER, whereas Zn deficiency occurs in 34% of cultivated soils of Assam plains and in about 55% soils of the hilly areas of the NER. Direct and residual effects are observed in B and Zn application to crops grown in deficient (B and Zn) soils. Soil management such as liming and organic matter application increases the availability of B and Zn in acid soils. Residual effects of Zn, B, and lime or FYM amendments have also been observed. Micronutrient deficiency in acid soils may, therefore, be ameliorated through liming and application of organic manure.^[15]

Rainwater Management—An Integral Component of Sustainable Soil Management

Rainwater management in the NER is equally important for sustainable soil health and agriculture. The NER receives very high rainfall (>2000 mm annually). However, more than 75% of rain is received within a short span of 4–5 months (June to October). Later the rains are deficient, causing a scarcity of even drinking water in the highest rainfall receiving NER (Cherrapunjee–Mawsynram range of Meghalaya receives about 11,000 mm rainfall annually). Crop fortunes are linked to the behavior of rains, and quite often there are crop failures even for want of life-saving irrigation at the critical stage of crop growth as the irrigation development is almost nil. Under such situations, it is important to harvest the rainwater where it falls. Watershed approach, microrainwater harvesting structure (*Jalkund*), roof water harvesting, *in situ* rainwater management, etc. have been recommended for efficient soil and water management in sloping lands of the Himalayas.^[16,17]

CONCLUSION

The management approaches for the soils of the NER should be site-specific and as per the resources available to a farm community. Since the region is a mix of plain, valleys, and steep slopes, the problems and opportunities are also site-specific. Thus, integrated natural resource management comprising IFS, INM, and AFSs along with the adoption of principles of conservation agriculture, and rainwater management offers the most sustainable soil management approach for the NER.

Macroporosity

Daniel Gimenez

Department of Environmental Sciences, Rutgers University, New Brunswick, New Jersey, U.S.A.

Daniel Hirmas

Department of Geography and Atmospheric Science, University of Kansas, Lawrence, Kansas, U.S.A.

Abstract

Macropores constitute a small volumetric fraction of the total porosity of soils but profoundly influence both the movement of water when soils are at saturated or near saturated states and the flux of gases when soils are at moisture states less than saturation. Macropores are recognized as one of the causes of preferential flow, a phenomenon that continues to defy our ability to predict transport processes in field soils. This entry reviews the most salient properties of soil macropores, including their origin and morphological properties, field and laboratory characterization methods, and strategies used to model flow of water through macroporous soils. Applications of geophysical and multistripe laser triangulation techniques to map macropores in the field, together with the increasing availability of high-resolution 3-D computer-aided tomography, are promising developments that could help improve the theoretical foundation of transport processes in soils containing macropores.

INTRODUCTION

Macroporosity refers to the areal or volumetric proportion of macropores in soils. The term macropore conveys connotations of rapid pathways for water, chemicals, and gases in soils. The Glossary of Soil Science Terms^[1] defines macropores as pores with an equivalent cylindrical diameter larger than 75 μm ; however, the range of sizes found in the literature for defining macropores varies between 30 and 3,000 μm .^[2] The hydrological properties of macropores are not only dependent on size but also on their continuity, tortuosity, and shape.^[3,4]

Densities of macropores reported in the literature vary from 10 to 10,000 pores/ m^2 ,^[5–7] and the distribution of their sizes is highly skewed, with the number of pores decreasing exponentially as their size increases.^[5] Larger pores tend to have elongated (planar or tubular) shapes whereas smaller ones are more rounded.^[8] Macropore density and continuity decrease with depth and are usually interrupted by tillage.^[7]

ORIGIN OF MACROPORES

Macropores can originate from cultivating a soil, fauna activity, root decay, shrinking of a soil matrix upon drying, or dissolution of chemical substances. Aggregation may result in a bimodal distribution of pores, where the larger pores are located in between aggregates (interaggregate pores). Tillage operations result in the formation of

structurally unstable macropores that subside during the growing season, thus altering the distribution of pore sizes in a very short period of time.^[9,10] Among soil fauna, earthworms have received much attention because of their abundance and potential impact in creating preferential flow pathways in soil,^[6,11] but fossorial fauna can also create extensive systems of burrows affecting large areas.^[12,13] Another source of biopores is plant roots, which can form an intricate network of macropores influencing water movement and chemical transport.^[14,15] Taproot systems are particularly effective in providing stable and continuous pores that increase infiltration rates.^[16] Shrinking of a soil matrix upon drying forms planar macropores that are important for transport processes in initially dry soils.^[4]

QUANTIFICATION OF MACROPORE PROPERTIES

Direct quantification of macropore abundance (number and volumes), sizes, and spatial distribution in the field is achieved by tracing or photographing macropores on planes parallel or perpendicular to the soil surface.^[7] Dyes are sometimes used to enhance the identification of continuous macropores.^[17] An alternative to the use of dyes is to cast the macropores with a viscous fluid that hardens with time and to subsequently excavate and quantify the hardened cast.^[18] Materials used to cast pores include epoxy, plaster, wax, and molten metal.^[19,20] Multistripe laser triangulation (MLT) scanning has been applied to quantify

Fig. 1 MLT scanner (foreground) being used to digitize macropores in the bottom portion of an excavation wall. The parallel laser stripes projected from the scanner can be seen on the pit surface in the background. For scale, each laser stripe is approximately 40 cm in length.

interpedal macropores from vertical walls exposed by excavation.^[21] As the lasers sweep across the exposed surface (Fig. 1), interpedal macropores act as “traps” of the signal, creating data gaps in the digital surface mesh that can be projected in 2-D and used to map and quantify the abundance, orientation, distribution, size, and shape of macropores. Non-invasive geophysical methods have also been applied to map subsurface macropores, but detection is limited to macropores of several centimeters in diameter.^[22,23] Laboratory techniques are restricted in the soil volume that can be evaluated but are capable of producing high-resolution images. Among these techniques are the use of resin-impregnated soil^[24] and X-ray and gamma-ray computed tomography.^[25,26] The number of studies using the latter technology has increased steadily since the early 1990s, as the instruments have become more accessible to soil scientists.

Indirect quantification of macropores has been made through measurements of infiltration at various suctions and of air permeability.^[27] These methods require defining a lower limit of macropore radius, which is typically influenced by the methodology used.

IMPACT OF MACROPORES ON WATER MOVEMENT AND CHEMICAL AND GAS TRANSPORT

Typically, more than 70% of the total water moving through a soil is transmitted through pores that represent less than

1% of a soil volume.^[28] The effect of macropores on water movement through soil was recognized in the late 19th century but received increased attention during the 1980s because of the risk macropores pose to contamination of subsurface water.^[2,3] In the presence of macropores, matter can bypass the soil matrix. For instance, heavy rainfalls occurring shortly after a chemical application can leach below the root zone up to 5% of the applied mass in sandy and loamy soils,^[29] but deep transport of chemicals has also been observed in heavy clay soils.^[30] Flow regimes influenced by macropores have been studied in relation to the transport of chemicals, microorganisms, and colloidal particles through soils,^[31–33] using both undisturbed soil^[26,33] and packed soil containing artificial macropores.^[34] Maximum flow is obtained under ponded conditions and with macropores connected to the surface, but macropore flow can also occur under a non-ponded regime once the macropore walls are wet.^[3]

Macropores also impact the exchange with the atmosphere of gases that are produced or consumed in soils as result of nutrient cycling (e.g., nitrogen and carbon). The effect of macropores on gas transport is more pronounced in soils with water contents near saturation. Under those conditions, only macropores are air filled and provide open pathways for gas exchange in the form of diffusion or mass flow. For instance, the flush release of methane following postharvest drainage of rice paddies is facilitated by the presence of macropores that allow gases to bypass the water-saturated soil matrix. Experimental observations in packed and undisturbed soils indicate that diffusion coefficients in soil around macropores are several fold greater than the average diffusion coefficient of the soil matrix.^[35]

Modeling Transport Processes in Macroporous Soils

Prediction of transport processes through macroporous soils is complicated by the intricate geometry of macropores. Laminar flow of water through pores with cylindrical and planar geometries can be theoretically estimated using Poiseuille’s equation modified to account for the finite nature of planar voids^[36] and the turbulent or transitional nature of flow through macropores.^[37,38] Preferential flow has been modeled as films of uniform thickness flowing along the surface of macropores as laminar flow.^[39] Prediction of flow through natural macropores is, however, highly complicated by their irregular shape. The use in flow equations of measured diameter, length, and volume of macropores does not satisfactorily predict macropore hydraulic properties,^[37] probably because the smallest section of the irregular macropores has a disproportionate effect on the flow of water through macropores and, therefore, a potential to influence geometrical estimations from flow measurements. The prediction of flow through macropores may be aided by studies replicating the complex geometries of

these pores through the use of rapid fabrication techniques such as 3-D printing.^[40,41]

Conceptual models of flow through macroporous soils divide the soil matrix in two or more domains with or without exchange of mass among them.^[3,4] The experimental determination of the relatively large number of input parameters needed to simulate multiple flow domains is a significant challenge for the application of these models.^[42] A more pragmatic approach to modeling water movement and gas transport in macroporous soils is to work with the concept of an effective porosity (i.e., the proportion of a soil volume occupied by macropores) coupled with relative simple relationships to estimate transport coefficients. Effective porosity can be determined in a number of ways from areal macroporosity mapped in the field to laboratory measurements of air-filled porosity at an arbitrary pressure potential close to saturation. Power law relationships between effective porosity and saturated hydraulic conductivity or air permeability can be used to predict these properties or to compare the characteristics of macropore systems.^[43,44] Similarly, Eck et al.^[45] coupled the size of macropores determined from MLT scanning with coefficient of linear extensibility to predict saturated hydraulic conductivity. These approaches are promising and require minimal data but do not provide information on mechanistic relationships between macropore morphology and water flow.

CONCLUSION

Macropores are ubiquitous in soils, and despite their minuscule volumetric presence, their influence on soil hydrology and gas exchange is profound. Their intricate geometry and multiple origins complicate any attempt to generalize their effect on water movement and chemical transport through soil. Despite the complexities of transport processes in the presence of macropores, advances in measurements techniques and in conceptual models have improved our ability to simulate transport of matter through soils with macropores.
